INTRODUCTION TO THE THIRD EDITION

With this edition, MODERN CLINICAL SYPHILOLOGY almost attains its majority (1926–1944). The first edition was a personal write-up in the days of American syphilology's youth. The second edition was a cooperative enterprise within the Pennsylvania group, aiming at an evaluation of the whole syphilologic field. The third edition, confronting the maturity of American syphilology and its preeminent contributions, has ceased to be an affair even for one-man guidance, and has become a full-fledged near-encyclopedic collaboration. It is not possible to separate, itemize or initial the individual contributions of Stokes, Beerman, Ingraham and their associates.

The original purposes of MODERN CLINICAL SYPHILOLOGY have been adhered to—to produce a single-volume, comprehensive summation of diagnosis and treatment, vivid and readable as well as factually authoritative and up to date, complete to within the well-known 99.44 per cent purity standard and reasonably reflective not alone of the authors' views but of the literature. We have been repeatedly urged to incorporate full bibliographic references. This is impossible in one volume. And the fate of two-volume works is that they reach only the desks of specialists, whereas *syphilis is a practitioner's problem.* We have, however, in the third edition, given references of the past ten years à date in parentheses to aid in consulting the standard bibliographic works. The enormous increase in syphilologic knowledge, especially of treatment, and the earthquake of penicillin have made the revising of a book at this moment a hazardous undertaking. We are convinced, however, that old and new must mingle for another ten years before the arsenicals pass, perhaps with late and even early syphilis, into limbo. The principles have a touch of the immortal, though the facts shift and change.

The critical need for condensation to meet increasing costs and scarcities has had to face the inescapable expansion of the subject. The book is a genuine tribute to the generosity of the publishers and their many ingenuities in the technic of their craft. The book unavoidably contains much fine print, and omits some matter, referring the reader to previous editions. We plead in extenuation of length and fine print that it also contains a great deal of information—so much that the authors might justly quote Herbert Spencer when he said that no man is the equal of his book. The attempt to write simultaneously for the student, as illustrated in the summaries and the principles for the practitioner, as illustrated in details and cases, and for the expert, as shown by the discussions and references to the literature, really telescopes three books into one.

Approximately 75 per cent of the text has been rewritten. The penicillin chapter and the account of syphilis in public health and military medicine are new. The chapter on prenatal, now largely called congenital syphilis, has been expanded and rewritten. The progress of serologic diagnosis, forward and backward so to speak, has been reflected in extended space devoted to the biologic false-positive reaction, so disturbing to doctor and patient these days. Every important technic of treating syphilis gets, we believe, full detailed and practical discussion. The final chapter on the detoxicants and

penicillin represents the first textbook summation of which we know that makes accessible information on this agent in the field of syphilotherapy It is a privilege to acknowledge the generosity with which the giants in the exploratory field like Mahoney and Moore, have made their thinking and results accessible to us. We have a few of our own co-workers to whom also we point with pride. The Penicillin Panel of the Venereal Disease Subcommittee and the Committee on Chemotherapeutic and Other Agents, with the Committee on Medical Research of the National Research Council have released information to us literally up to the last minute of the publishing deadline. The Journal of the American Medical Association has been similarly generous in permitting extended quotation of recent papers The courtesies of many others are specifically noted

Previous editions have not failed to draw criticism both for too many words in general and too few or none about something in particular We hope comment and criticism of this sort will continue—to keep us on the alert. The subject index of the third edition is by Stokes, who hereby assumes responsibility The Secretary of the Department of Dermatology and Syphilology and the Institute for the Control of Syphilis, Miss Virginia MacElroy has contributed greatly by ingenuity and meticulous accuracy to the many text summaries, the manuscript and the index

The inspirational closing sentence does not easily come to us. We may perhaps take comfort and courage however in the way in which a book like this records the impending extinction of a centuries old plague in the short space of two decades and reflects the advance in mankind s most noble war—the battle to achieve the ideal— *Mens sana in corpore sano*

+++	3 plus (positive)
V	Used in the Index to imply discussion of differential diagnosis

Modern Clinical Syphilology

CHAPTER I

THE FUNDAMENTAL BACTERIOLOGY PATHOLOGY AND IMMUNOLOGY OF SYPHILIS

The syphilology of the nineteenth century was fundamentally clinical that of the first three decades of the twentieth century has found its inspiration primarily in the laboratory under the presiding genius of Schaudinn of Metchnikoff and Roux of Bordet and Wassermann of Neisser of Ehrlich

Underlying the tremendous advances of modern treatment are of course, fundamental experimental contributions. Complex and difficult though the fields of experimental reasoning and observation may appear to the onlooker it is here unhesitatingly urged upon every student of syphilis that a systematic and earnest effort be made to grasp such part of the fundamental principles underlying the clinical behavior diagnosis and treatment of syphilis as may be introduced into a work of this kind No one who has had even a limited experience in answering the questions on which students and physicians seek information in their practical contacts with the disease can fail to realize that the great ailment of modern syphilological practice is a lack of comprehension of the why and wherefore rather than the "what to do.

A Definition of Syphilis.—Syphilis is an infectious disease due to *Spirochaeta pallida* of great chronicity systemic from the outset capable of involving practically every structure of the body in its course distinguished by florid manifestations on the one hand and years of completely asymptomatic latency on the other· able to simulate a large proportion of the entities comprising the field of medicine, surgery and the specialties transmissible to offspring in man transmissible to certain laboratory animals and treatable to the point of presumptive—but not, thus far demonstrable—cure by the use of derivatives of arsenic mercury bismuth the iodides and nonspecific or fever therapy To this range and to this essentially Machiavellian facility in disguise deceit and malevolence we owe an interest in syphilis among medical and scientific men everywhere which is all but unique and which is the mainspring of much of the progress already made against it.

SPIROCHAETA PALLIDA

Fritz Schaudinn, the parasitologist, assisted by the syphilologist F Hoffmann, identified in March 1905 the spiral organism which is today accepted as the cause of syphilis from an unstained specimen with a relatively low-power microscope without darkfield The succession of organisms credited briefly as responsible since the disease was first recognized as an infection and the fascinating story and reasoning underlying the life cycle concept are excellently reviewed by Ingraham (1932) The term "*Spirochaeta*

pallida supported by clinical usage is here employed in preference to the more exact but less familiar term "*Treponema pallidum*" of the laboratory

The inter-relations among spirochetes include many points of importance for comprehension of the biology of syphilis. Bessemans (1936) points out that morphologic differences among spiral organisms are less important than functional or pathogenetic differences. *Spirochaeta pallida*, *Spirochaeta pertenuis* (yaws) and *Spirochaeta microdentium* (a mouth saprophyte sometimes credited with producing gingivitis) resemble each other very closely There is evidence that the spirochete of yaws (*Sp. pertenuis*) produces an infection which sometimes protects against syphilis (Turner (1936) Chesney (1934)) Kolmer and Eagle believe that the Reiter spirochetal antigen which is quite effective in a complement fixation test for syphilis (Pallgen) contains not *Spirochaeta pallida*, but *Spirochaeta microdentium*.

Bessemans lists differences in virulence and behavior between *Spirochaeta pallida* in lymph nodes as compared with the same organism in the testicles of rabbits. He believes that the brain-

Fig. 1 —*Treponema pallidum* in orchitis Stained by Levaditi method (× 1000) (Collection of Dr Noguchi.)

accustomed *Spirochaeta pallida* of paresis has lost its virulence for animals; mentions six other evidences that there are functionally different varieties of *Spirochaeta pallida* under common or very slightly variable morphology Bejel which Hudson (1936) maintains is the yaws-like mild form of syphilis among the Bedouins is thus interpretable (Bessemans) as a functional variable of morphologically constant spirochete. Morphology thus becomes critical chiefly in the differential elimination in the darkfield of saprophytic spirochetes that may be confused with *Spirochaeta pallida*. These include especially mouth spirochetes (*Spirochaeta buccalis*, *Spirochaeta intermedia* or *macrodentium*, and *Spirochaeta dentium* or *microdentium*) The larger types include also *Spirochaeta vincenti* The genital types whose differential morphology must be studied, include *Spirochaeta refringens*, *Spirochaeta calligyrum*, and *Spirochaeta cuniculi* of rabbits, whose confusion with "thick" form of *Spirochaeta pallida* betrayed Levaditi and Marie (1923) into the first fallacious morphologic description of neurotropic strain of *Spirochaeta pallida*. *Spirochaeta cuniculi* produces easily distinguishable lesions in the rabbit, and is not pathogenic for man. While some confusion has undoubtedly been introduced into the earlier experimental work on rabbits by the non-recognition of *Spirochaeta cuniculi* infection, Nichols and Walker believe that this need not be greater or more significant than that introduced into the study of tuberculosis

by the existence of other acid-fast organisms such as the smegma bacillus. Pinta, formerly regarded as tropical cutaneous mycosis, is apparently produced by spirochet indistinguishable morphologically from *Spirochaeta pallida* (Saenz, Gra Triana and Alfonso Armenteros (1938), Pardo-

Fig 2.—*Spirochaeta pallida* as seen with the electron microscope lth t lateral protrusions, one of hich is show very clearly t be made up of small spherical bodies. Meserow sky observation that stalk often carries more tha one minut bud led him t conclude that the buds have the property of dividing (Stral P190B (88a) × 14,000.) (From H. E. Morton nd T F Anderson Am. J Syph., Gonor and Ven. Dis. 26 563 1942.) (Courtesy of Dr Harry E. Morton.)

Fig. 3.—A view of *Spirochaeta pallida* under the electron microscope showing continuous envelope or membrane also end knob (From U J Wile, R. G Picard, and E. B Kearny J.A.M.A. 119 880 1942.) (Courtesy of Dr Udo J Wile)

Castello et al. (1938 and 1940)) (See Beerman, 1943) In clinical syphilologic practice the mouth spirochetes present very much more difficult differential problem than any other and one which greatly increases the uncertainties in darkfield diagnosis of mucous membrane lesions. Differential details are discussed under darkfield and staining.

Morphology —Schaudinn s original description of *Spirochaeta pallida* is still accepted today as in Ingraham s review (1938) "The length varies from 4 to 10 micra, the average being about 7 micra, as shown in comparison of the spirochetes with the blood corpuscles in their midst. The number of windings varies from 3 to 12 (Schaudinn later admitted a limit of 14 and finally of 26) The average number has been shown repeatedly to be between 6 and 14 The organism is seldom if ever more than 0.25 μ in thickness The average relation of width of spirals to length of turns is 1:2 Schaudinn, in his original description was able to define not only a certain amount of structure but to recognize the (double) flagellum at each end of the organism As revised by the recent descriptions of *Spirochaeta pallida* by Morton and Anderson (1942) and by Wile Pickard and Kearny (1942) using the electron microscope (it must be recalled that this is a dry preparation of *Spirochaeta pallida*) the primary spirals have a width of from 0 4 to 0.55 μ with a pitch of about one μ. Initial constriction of the spirochetal body suggests the beginning of transverse division, leading eventually to two spirochetes held together by a tenuous filament which may be the unstained segment observed by other workers in stained preparations. After the separation of the two spirochetes at this point the thin filament may persist as the frequently observed terminal filament.

Amorphous material has been found about the spirochetes in certain preparations This is not to be confused with the flagella like filaments, or tendrils (Wile and Kearney 1943) projecting from the sides of the organism or with the terminal filaments which appear to be definite structures. Dense spherical bodies are frequently observed within the bodies of the spirochetes Similar but larger dense spheres are also observed to protrude from the body to be attached by a stalk, and to appear as clusters attached to the body or separated from it. Such clusters were also described by Mierowsky (1913 1941) Ingraham (1938) remarked on the prolonged discussion which has resulted from distortions of form and groupings of spirochetes in their possible relation to the mode of reproduction Manouélian (1940) states that the organism divides transversely into two, three or four parts, each of which represents a new organism or a granule may be detached from the body of the spirochete by the same process of transverse division These granular forms remain attached to the spirochete by means of a filament, which with the granule finally breaks away from the organism. Atypical granular forms are often found in the lesions of syphilis, such as gummas aneurysms, and lesions of early congenital syphilis They are also found in early lesions after antisyphilitic treatment. *Spirochaeta pallida* has a highly characteristic motility analyzable into three elements a motion of translation in the direction of the long axis a slower revolution or rotation of the spiral like a corkscrew on its own axis, and a waving or twisting motion from side to side The notable and distinctive characteristic of the organism which will be mentioned later is its ability to hold the coil of a spiral without wave motion or flattening

A warning should be given all students of the morphology and behavior of *Spirochaeta pall d* f the ever-present pitfall of artefact. Imitations of spirochetes capable f deceiving the inexperienced and even usable for teaching purposes, l been described by Eberson, and a formula for the preparation of artific al spirochetes has recently been devised

Life Cycle and Involution Forms.—The question of the life cycle of *Spirochaeta pallida* under discussion since Schaudinn's original studies, still remains in an unsettled state. Students of the problem should read in full Ingraham (1938) on the subject, and Olsen (1938) and should include of course the observations of Warthin and Starry, Saleeby and Greenbaum, Levaditi, Manouélian, Bessemans (1936). The practical interest of the question concerns of course the existence of a resistant form of granular or ultramicroscopic type, capable of being concealed within so small an object as the spermatozoon or the virulent pulp of apparently spirochete-free lymph nodes. O'Farrell and Balfour connected the shedding of granules by *Spirochaeta pallida* and *Spirochaeta refringens* with the action of 606. Ringed forms have also been given involutional importance in tissue and Olsen mentions as a special type the small form of *Spirochaeta pallida* observed in syphilitic aortic lesions. Noguchi succeeded in demonstrating the really remarkable range of confusion possibilities among spirochetes which must constitute a possible pitfall in any diagnosis or reasoning based purely upon cultural or involution characteristics. Kendall has shown that certain microorganisms, including the *Spirochaeta icteroides* (yellow fever) can by suitable nutritive conditions be passed through an ultramicroscopic state.

Cultivation of Spirochaeta Pallida and the Laws of Koch.—The situation to date (1943) can be summarized by the statement that all the laws of Koch have been satisfied except that of cultivation of virulent *Spirochaeta pallida*. Competent observers have repeatedly claimed success in this undertaking, but confirmation has been unsatisfactory. Gammel and Ecker (1931), and Kast and Kolmer (1940) rated the problem as still unsolved. It should be recalled that cultivation of the organism and cultivation of the virulent organism are two distinct undertakings. Schereschewsky in 1909 is now generally credited with having been the first to cultivate the organism successfully. Wile and Snow (1941) applied the chorio-allantoic membrane of the chick embryo technic to the problem with what they regard as two successful experiments. They were unable to demonstrate spirochetes in the infectious chick tissue and compare their findings in this particular with the absence of organisms in the infectious popliteal lymph nodes of rabbits and the viscera and brain of the mouse. Sterzi and Staudecher (1939) used the chick embryo method unsuccessfully. Loren Shaffer showed that it was possible definitely to increase sometimes enormously the number of *Spirochaeta pallida* in tissue removed from syphilitic animals by anaerobic incubation for from forty-eight to seventy-two hours.

Experimental Syphilis in the Animal.—The study of experimental syphilis in the animal, despite its limitations, has made possible the advances of the twentieth century as contrasted with the clinical era of the nineteenth. The work of Metchnikoff and Roux and the epochal studies of Neisser, many of which have been merely repeated by subsequent investigators were undertaken on the ape, necessitating in Neisser's researches a completely equipped scientific expedition to Java, in order to tap an adequate reservoir of animal material. Finger, Uhlenhuth, Mulzer, Brown and Pearce and Chesney, Kolle, Levaditi, Kolmer and Truffi are perhaps the senior immortals in the contributions made by experimentation in the rabbit. Schlossberger, Turner, Kemp, Rakies and Severac, Klauder, Beerman, Greenbaum, Bessemans, Brandt, Eagle, Parner are representatives of the most recent developments. To the study of the disease in the rabbit the clinician owes what conception he has of the influence of age, sex, constitution, season, infective dose of organisms, diet and endocrine activity on the course of the disease. The conceptions of the asymptomatic carrier have been greatly expanded by Kolle and his successor Schlossberger not only through the study of asymptomatic infection in rabbits, but its practically unvarying occurrence in the mouse, which following Schlossberger and Rankes and Severac's exploration of the possibilities, has provided the means not only to modify the characteristics of the organism with respect to tropism for such structures as the nervous system, but also to provide an invaluable biological filter through which a new strain of organism can be passed from man to the rabbit. The influence of site of inoculation on the course of the syphilitic infection is an animal contribution; the demonstration of the successive barriers of defense and fields of reaction in the body tissues are products of animal studies. For the chemotherapeutic attack upon syphilis, the experimental animal has provided much, though less than might have been hoped for. As the toxicity test-tube so to speak, with trypanosomes for index purposes, the mouse has supplied the modern chemotherapeutic indices, slowly replaced by the study of spirochetal effects and cure in the rabbit. If anything, there has been something of a tendency to overdo the transfer of toxicity and chemotherapeutic effect as worked out in animals to the anticipated behavior of drugs in man. It is now clear that there are important and in fact, the most important, groups of toxicity reactions in man which have no homologues in animals and in which animals cannot be used to predict the clinical effect. The effect of trauma on the localization of syphilitic lesions, incontestably established for animals as for man, still remains, as far as mechanism is concerned, an unsolved riddle. It deserves to be emphasized that animal syphilis is the domain of experts and that confusion and inadequacy await the inexperienced in their efforts to transfer the human

infection to the animal experimental subject. The technic of animal inoculation described in previous editions is therefore now omitted, and those whose clinical opportunities bring them valuable strains of resistant or biologically distinctive syphilitic infection for study should immediately seek the aid of one or another of the recognized experts in the animal field, rather than to attempt animal inoculation for themselves.

Sub-varieties or Strains of Spirochaeta Pallida.—While abundant question has been raised as to the identity of the cultured *Spirochaeta pallida* with *Spirochaeta pallida* of human syphilis, no reasonable doubt remains as to the identity of the organism associated with animal syphilis and the *Spirochaeta pallida* in the syphilis of man. In fact, the crucial demonstration of the infection of human laboratory workers with syphilis by *Spirochaeta pallida* being carried in rabbits has several times, unfortunately been made (Wakerlin, Shaw 1941) The Nichols and the Truffi strains have now been carried in animals to the point where they may be regarded as having positive identities. A number of less well-known strains are used in Europe. Neurotropism, the first pathogenetic functional peculiarity to attract attention as a strain characteristic, has now been traced through the work of Schlossberger and of Raiziss and Severac, to the important biological principle that prolonged residence in type of tissue or environment is capable of developing tropism and adaptation in *Spirochaeta pallida*. Thus, sojourn in the brain tissue of

Fig. 4.—Typical chancres of the rabbit testes. (Collection of Drs Brown and Pearce.)

mice, has been shown to prepare the Nichols strain of *Spirochaeta pallida* for the development of neurotropic reaction in the rabbit. Kolle and Schlossberger pparently succeeded in carrying the differentiation of strains and the detection of strains of greater and lesser virulence in animals by immunologic methods to the point where a superinfection ith second strain could be produced in given animal, and the original strain and the superinfecting strain subsequently recovered and identified by animal reinoculation. Kritschewsky demonstrated strain characteristics for *Spirochaeta recurrens*. Beerman and Severac have been fortunate in maintaining an arsphenamine-resistant strain of *Spirochaeta pallida* recovered from treatment-resistant patient, through 87 generations (1936 1938, 1942)

For the clinician these observations have as yet little clearly defined meaning. Strain characteristics and tropism have been suspected in conjugal tabes and paresis in which husband and ife infected by the same organism (presumably) developed the same manifestations of the disease. Famous examples of neurotropism in hich 5 or more persons infected by the same woman all developed paresis, are cited in Chapter XX. Dermotropism as opposed to neurotropism has been a much labored conception in clinical as ell as experimental syphilology I Wile and Belote study of this question the histologic and pathogenetic differences between the alopecia associated ith presumptive neurotropism and the follicular infiltrative syphilid

are well brought out. It cannot unfortunately be said that clinical conceptions of syphilis have thus far derived much from the experimental investigation of strains.

Rate of Invasion, Route of Distribution, Identification of Spirochaeta Pallida in Body Tissues and Fluids.—Granted that the conditions prevailing in the experimental infection of animals by direct exposure of the intact body surface to *Spirochaeta pallida* are comparable to those in man, Mahoney and Bryant (1933, 1934) have apparently determined under the best control conditions that *Spirochaeta pallida* invades the genital mucosa (rabbit prepuce) between the third and fourth hour after the organisms are placed on the surface. Soap and water cleansing and other forms of disinfection conveyed protection against infection in exposures as long as two hours, but not as long as three hours. Strong antiseptics including alcohol and iodine, were somewhat more effective up to three hours, but useless thereafter. Ko (1933) was unable to demonstrate infection through the uninjured skin of mice. The literature on the rate of invasion of the lymphatics and blood stream by spirochetes gaining entrance from inoculated fragments of tissue, intratesticular injections and so forth is reviewed by Raiziss and Severac (1937), the shorter

Fig. 5.—Twin chancres in man, produced by contact inoculation. The two lesions can be exactly superposed.

periods range from one-half, one, two, seven, and twenty-four hours after inoculation, up to the time of recognition of organisms in the adjacent lymph nodes. Kolle and Evers (1926) were able to demonstrate the presence of spirochetes in lymph nodes of guinea pigs five minutes after inoculation. The traumatic quality of many of these inoculation experiments must of course be recognized. Tani, Ogiwara, Hatakeyama and Oya (1933) found that spirochetes rubbed into scarifications in the scrotums of rabbits appeared in the inguinal nodes within five minutes and in the blood in an hour. It is evident, therefore, that where trauma of any description paves the way, dissemination of the infection is exceedingly rapid, and the disease is indeed systemic from its very inception. Observations such as these have the clinical significance of doing away with long practiced excision of the chancre in the effort to remove the local, supposedly isolated, focus of spirochetes at the onset of the disease. Levaditi, Vaisman and Rousset-Chabaud (1936) grafted bits of rabbit testicular syphiloma on the backs of mice which were killed at intervals of from two to forty-two days. Histologic study of inoculated areas showed that spirochetes had entered the neighboring lymphatics by the second day; by the forty-second day there was a generalized infection of the lymphatic system. Spirochetes are also present in the walls of the blood vessels

of the infected region on the first, third and fifth days and blood from infected mice was infectiou for rabbits, one three t lve and thirty-five days.

Tw routes of distribution of the organism are clinically important distribution by way of the lymphatic system and distribution by way of the vascular system Both are discussed under elective localization. *Spirochaeta pallid* has been identified in the normal skin of persons with early syphilis (primary and secondary) (Frankl, 1930 nd Charpy 1937) Charpy identified the organism in lymph from scarified sit on the mucous membrane of the glans penis before the development of the chancre. Levaditi, Storesco and Vaisman (1936) on the other hand found that very little dispersion of organisms from the skin took place in experimental animals and ma Frazier and H (1933) demonstrated the presence of *Spirochaeta pallida* in tumor histologicall diagnosed subcutaneous sarcoid of Darier Roussy in a Chinese patient ith syphilis. Among other tissues in which *Spirochaeta pallida* is easily and quickly identified following infection should be mentioned the testis, spleen and bone marrow as originally established by Neisser Javanese work, the organisms appearing t these sites within twenty-four hours after inoculation. It should not be forgotten that the identification of spirochetes in tissue as reported for example by Freedburg and Barron (1940) in the human gastric mucosa by no means establishes their identity as *Spirochaeta pallida*. The experimental work in seminal transmission of syphilis has run foul of failure t control this factor of error according to Parlser (1940–1942) recent critique. Morphologic differentiation of organisms must be confirmed by experimental inoculation and distribution studies t validate the findings. Thus Dormanand Sahyun (1937) identified what they believed t be morphologically typical *Spirochaeta pallida* in foci conforming to Warthin descriptive criteria, but the confirmation of the identity of the organism remains nonetheless incomplete. Kemp and Rosahn (1937) by intravenous injection of spirochete emulsion in rabbits secured inoculation of placentae yet the placenta proved to be absolut barriers to the infection of the rabbit fetuses. The fact that the distribution of *Spirochaeta pallid* through tissue barriers is not merely matter of inoculation or contact, was interestingly demonstrated by Raison and Severac, who found that inoculation of the organism into the cerebral ventricles of rabbits resulted in the development of testicular hancre rather than direct inoculation of the adjacent nervous system tissues nd meninges. The belief that such shortening of the rout of invasion occurred in inoculations about the face hich were supposed to lead to an increased incidence of cerebral syphilis has not been established Wagner (1931) failed to demonstrat any direct passage of an experimental infection on the rabbit cornea to the tissues of the adjacent nervous system.

Of the body fluids, the blood contained the organism, according to Frazier and Pian recent review (1930) as early as twenty days before the appearance of the chancre in Chinese male blood donor Moore (1933) observed two cases in which the blood was proved to be infectious during the seronegative primary stage. The animal experimental evidence indicates (Brown and Pearce, 1920) that 0.5 cc. of blood one week following intratesticular inoculation, will transmit infection t normal rabbits. Raison and Severac demonstrated the appearance of spirochetes in the blood after intratesticular inoculation in as short period as five minutes. Uhlenhuth and Mulzer (1913) and Früh ald showed that the blood in the primary stage of syphilis, transmits the disease in 81.2 per cent of cases, nd in secondary syphilis, in 75 per cent of cases. Frühwald and number of other observers have confirmed fully the infectiousness of the blood in the seronegative primary phase of the disease Frühwald also demonstrated the infectiousness of the blood in latent syphilis. I contrast, and illustrating the range of variation which must be allowed for in clinical generalization, particularly involving blood transfusion, McNamara was forced by circumstances to use the blood of six lat syphilitic Negroes in nineteen transfusion for ten recipients, and as unable to demonstrate single transfer of the syphilitic infection under such circumstances. The entire problem of syphilis transmission by blood transfusion will be subsequently discussed. The clinical principles involved may be tersely st ted no recent advances such as the demonstration of protection afforded b admixture of blood or serum with the arsphenamines alters the clinical principle that to use the blood or serum, cerebrospinal fluid or tissues of person know t have had syphilis, in any form of biological treatment in ma without adequat sterilization and without the fullest practicable precautions against the presence of syphilis in the donor is reprehensible

Th cerebrospinal fluid is know t contain *Spirochaeta pallida* under variety of circumstances. Nichols and Hough est blished the famous Nichols-Hough strain of *Spirochaeta pallida* in rabbits from the cerebrospinal fluid of patient ith early acut neurosyphilis Geiger found the organism in the fluid of tw cases of seronegative primary syphili It has been repeatedly found in the spinal fluid of syphilitics in hom the cell counts, globulin content, Wassermann reaction and colloidal test ere negative A summary of the reports in the literature indicates that the organism may be recovered in from 15 per cent t 40 per cent of normal spinal fluid

in early syphilis. Pearce H and Mu (1936) report very interestingly their failure to demonstrat *Spirochaeta pallida* in the cerebrospinal fluid of forty-two syphilitic Chinese patients. In Chesney and Kemp cited series (1924), special precautions were taken to void confusion with *Spirochaeta recurrentis*.

Saliva apparently contains *Spirochaeta pallida* only when syphilitic lesions are present in the mouth or throat. Animal experimental confirmation of this negative finding has most recently been furnished by Barnett and Kulchar (1939).

The finding of spirochetes in urine sediment is good illustration of the care that must be taken in excluding the possible presence of other *Spirochaeta pallida* in body secretions. Pariser (1944) points out that Stoddard, Patterson, Felsinger nd Huber and he himself have found spirochetal forms in urethral secretions which can be confused with *Spirochaeta pallida*. *Spirochaeta pallida* may also of course be present i rine from syphilitic lesions along the urinary tract, and particularly the urethra.

The presence of *Spirochaeta pallida* in semen has apparently been established by succession of investigations, beginning ith Finger Neisser and Uhlenhuth and Mulzer the source of the spirochetes ho ever seems t be the real question at issue Pariser (1942) in an extended and carefully controlled study of the infectiousness of semen in which the presence of spirochetes from urethral and genital lesions was as completely excluded as possible was unable t obtain positive inoculation. I other words, *Spirochaeta pallida* in semen is present therein by virtue of syphilitic lesions in the urethra or along the urogenital tract and not because it is present in semen as secretion. This would seem t set t rest, if confirmed, the belief that there is a rest form of *Spirochaeta pallida* capable of being carried in the sperm or semen and capable of transmitting the disease to the ovum instead of t the fetus through the mother Kemp has established for lat syphilis (1939–1944) the same principle, stated above, which Pariser established for early syphilis (1942)

The presence of *Spirochaeta pallida* in breast milk, of great importance in wet-nursing practices was apparently demonstrated by Uhlenhuth and Mulzer ho infected rabbits from the milk of three seropositive women otherwise free of symptoms. Sch arts has, however failed after careful search t find *Spirochaeta pallida* as such in breast milk.

Of great importance to the carrier problem in syphilis and to the practical epidemiology of syphilis is the question of the infectiousness of vaginal secretions in syphilitic women. Pariser (1940–1941) has most recently and extensively reviewed the literature and discussed his own experimental results. He concludes that virulent *Spirochaeta pallida* are discharged by the syphilitic woman into the vagina in the presence of local early or "late (more than four years duration) infection as relapsing phenomenon. I the absence of such lesions they are discharged only through the menstrual blood of the early syphilitic, or from an abnormal appearing cervix *in which instances it is probable that lesions are present within the cervical os or uterus.* The physiologic secretions are not infectious. Pariser was unable t give the absolute end point of the period of infectiousness or the frequency of cervical relapse, but found that it occurred at least six and one-half years after the definite onset of the disease.

Viability of Spirochaeta Pallida.—The anaerobiosis of *Spirochaeta pallida* and its inability to resist drying have probably spared mankind the absolute universalization of the disease. The distinction between virulence, preservation of motility and *preservation of form of Spirochaeta pallida in secretions* and tissues outside the body must be insisted upon.

Infectivity of *Spirochaeta pallid* in refrigerated citrated blood can be demonstrated up to about the third day (seventy-two hours) (Turner and Diseker 1941) Fresh citrated blood heavily seeded with virulent *Spirochaeta pallida* may undergo spontaneous sterilization in seventy-two hours when kept at 4 to 6° C. Plasma (citrated) is spontaneously sterile in twenty-four hours (Kolmer and Rule (1942)) Ravitch and Chambers (1942) found human and rabbit plasma (frozen)—20° C. for forty-eight hours or longer is not infectious for normal rabbits but is infectious when the freezing period is only twenty-four hours. Bloch (1941) observed that the organism in rabbit blood survives for as long as seventy-two hours at 5° C. Turner Bauer and Kluth (1941) showed that freezing desiccation kills *Spirochaeta pallida*. Zinsser and Hopkins found that the organism in darkfield preparations at room temperature by daylight died out in approximately eleven and half hours, and that this is approximately its life in secretions contained in moist handkerchiefs. Mahoney in studies of delayed darkfield technic, found that motility may be observed up t ninety-six and one hundred twenty hours or even longer after collecting the specimens, and that entirely recognizable forms were observed in an icebox preparation thirteen

days after collection. Harrison reported motility as late as thirty-four and even forty four day after preparation of slide specimen, and that specimen containing motile organisms could be shipped repeatedly back and forth across the Atlantic. Lacey and Haythorne found the organism still motile in autopsy material refrigerated for forty-eight hours, and were able to preserve motility in sealed tubes for specimens of syphilitic rabbit testicle as long as fifty-eight days. Syphilitic autopsy material was infective twenty-six hours after death the chancre twenty-four hours after excision syphilitic rabbit testicle twenty-four hours, but not as long as fifty-four hours after excision. Rosahn (1933) infected rabbits as late as seven days after excision of the testicular syphiloma but in no case after fourteen days. The organism dies quickly at 2 degrees centigrade cannot live below −10 degrees centigrade dies in seven to ten minutes at 45 degrees centigrade and five minutes at 60 degrees centigrade (Klemmeyer- Bronfenbrenner and Noguchi) More recent work by Turner (1936) indicates that infectious material from rabbits after freezing in the case of both syphilis and yaws, produces infection as late as four months after freezing. More recently Turner extended this period to a year at −78 degrees centigrade.

Thermal Death Point of Spirochaeta Pallida.—Boak, Carpenter and Warren (1932) determined by in vitro studies that *Spirochaeta pallida* was immobilized at 39° C. (102.2° F.) for five hours 40° C. (104 F.) for three hours; 41 C. (105 8° F.) for two hours and 41.5° C. (106.5° F.) for one hour Bessemans (1938) concluded that local temperature of 42° C. (107.6° F.), sustained for one hour or of 40° C. (104 F.) sustained for two hours, or even slightly lower temperature sustained for many hours, sufficed to bring about the immediate or gradual death of *Spirochaeta pallida* in the primary testicular syphiloma of the rabbit and in the external lesions of primary and secondary syphilis of man. In contradistinction t these results, *Spirochaeta pallida* of the popliteal lymph nodes of the syphilitic rabbit hardly ever lose their virulence if treated in vivo by heat for similar time interval sometimes it is necessary to destroy these germs, to sustain temperature of more than 40° C (114.8° F.) Klauder (1939) determined that it required t least t minutes to kill the organism when heated at 140° F (48 9° C.) in vitro.

Resistance to Disinfectants and Drying.—Soap has been shown by Reasoner to have a powerful germicidal and solvent action on *Spirochaeta pallida* even superior to that of many widely advertised disinfectants 1 1000 phenol kills the organism in fifteen minutes, while 1:20 formaldehyde which will kill *Staphylococcus aureus* and *Bacillus coli* in a five-minute exposure will not kill *Spirochaeta pallida.* 1:500 formaldehyde however is effective The sulfonamides are without direct destructive effect on *Spirochaeta pallida* (Pariser) The drugs employed in the treatment of syphilis (arsphenamines bismuth) have been shown by Eagle s work to be much more spirillicidal in vitro than the studies of earlier investigators indicated.

It is generally agreed that drying under any circumstances is almost immediately destructive of *Spirochaeta pallida*

Epidemiologic Considerations.—In dealing with the syphilitic patient as a problem in infectious disease it becomes evident then that the critical issue is the disinfection of the tissues of the host rather than the fomites Moist material become the only possible source of transmission, and this does away with the necessity for disinfection or special cleansing of rooms or dry fomites. On the other hand dressings with moist discharges objects such as pipes cups and instruments which may be passed from person to person may be extremely dangerous. Gaston and Commandon found that *Spirochaeta pallida* lives for 30 minutes on glasses washed only in cool water Even antiseptics may fail to protect where the organism is shielded by a dense precipitate of protein Cleansing therefore becomes a necessary pred ecessor corollary nd in many cases the entire mechanism of prevention and soap and wat nd especially soap achieve unprecedented importance in prophylaxis Th adaptability of *Spirochaeta pallida* to the conditions of invasion and und t bed parasitic existence in man is such that infection takes place too ofte when lea t expected and in spite of what may seem to

be all reasonable precautions Unawareness is therefore the great danger in encountering syphilis, and increases every type of risk in both physician and patient. The peculiarities of the organism explain the genital transmission of the disease for only about the flexures and in and near the mucocutaneous orifices are the requisite combinations of moisture erosion of lesions liberating spirochetes, and quasi-anaerobic conditions combined Syphilis is therefore inevitably a disease of intimate contact, and moreover of intimate contacts rendered unguarded by emotion by inconspicuousness or concealment of infective lesions by painlessness, by ignorance. Kissing and sexual intercourse are therefore the overwhelmingly frequent sources of acquired infection with syphilis. It is well worth while in discussing syphilis with patients whose perspective is much distorted with reference to the moral problems of the disease to direct their attention to this aspect of the matter It is not a divine moral purpose or a satanic punitive ingenuity that connects syphilis with genital activities, but a mere biological accident no more significant in the last analysis than the fact that potatoes grow in sandy loam The comparative infrequency of infection among those whose professional duties as physicians, nurses and dentists, bring them constantly and intimately into contact with the disease is only relative and the ever present risk to which members of these professions are subjected should never for a moment be forgotten

PARASITE HOST RELATIONS

Symbiosis.—The outstanding fact in the general immunological background of syphilis and one which Warthin in his teaching never tired of emphasizing is the extraordinary adaptation of the *Spirochaeta pallida* to its life in man. An organism which in nature affects no other species and which in the vast majority of cases is able to maintain its foothold in tissue literally through decades of almost symptomless infectivity meeting a wide range of growth conditions and therapeutic opposition with an almost unbelievable ability to survive every test, is easily one of the sovereign instances of parasitic adaptation in the entire field of disease. Experimental study has only served to expand our conception of the perfection of this symbiosis

The Syphilitic Carrier —Basing his position upon the now inescapable evidence of lifelong symptomless infection in the rabbit and mouse with complete absence of tissue reaction against the invading organism Kolle has proposed the theory that there exists in man not only the familiar clinical picture engendered by reaction against the organism but a state of complete carrier immunity or anergy against the infection Thus it may be conceived that there are human beings who have become carriers of syphilis without any outward sign of reaction either at the point of invasion or elsewhere in the body and that these persons live out their lives as carriers almost if not quite unaffected by the presence of the parasitic organism and even conceivably transmitting the disease or sustaining superinfection with a new strain practically without any form of tissue response That such infection as, for instance, of the lymphatic system of the rabbit, is well known to occur does not, however justify too ready transfer of principles established by animal observation to the case at hand.

The interplay between host and organism in syphilis is evidently an extremely complex affair It is extremely difficult to study it in man because it is rarely possible to control more than two factors, namely the strain of organism and the duration of infection, or those element,

in any given group of comparable cases. The commonest example, infection of husband and wife with the same organism, is weakened by the adventitious factors of sex, by passage through an intermediate host, usually the husband, before reaching the wife, and by variations in the behavior of infection dependent on the site of inoculation. For example, in the case of two brothers infected by the same woman at the same time, the two infections ran totally different course. One brother developed conspicuous chancre and definite secondary manifestations within the usual incubation period. The other developed three penile sores two weeks later than his brother. The lesions were cauterized, no secondary eruption developed and the systemic infection was discovered only when Wassermann test was made following the development of the brother secondary eruption. Both brothers were placed on the same treatment, the condition of the first one clearing up rapidly and apparently permanently: the other who had had no secondary eruption and whose immunity mechanism was presumably modified by that fact, nine months later presented the fulminating precocious disseminat recurrence of an inadequately treated early infection. In another instance under our observation, family group of four persons studied for five years and all infected with the same strain of organism, it was found that the father and one son presented highly resistant neurosyphilitic manifestations, and the mother and the other son had quiescent, benign but Wassermann-resistant infections. The familial resemblances in this group, so far as appearances go, support the apparent resemblances in the soil reaction t the seed, the two neurosyphilitic patients resembling each other in appearance. On the other hand, Livingood and Beerman (1941) record the similarity in course and outcome of single strain of syphilitic infection, transmitted by blood transfusion in two brothers, who ran resistant course despite the employment of two differing but theoretically adequate and effective modes of treatment

It must be apparent, therefore that the course of a syphilitic infection in any given case is controlled by numerous complex interacting factors whose proportionate relationships and significance are as yet only partly understood

Resistance and Susceptibility—Morgan (1941) following Chesney s suggestion diagrammed the possible clinical course of syphilis, allowing 33 per cent to 35 per cent asymptomatic infection with 25 per cent to 35 per cent spontaneous "cure within the first twenty years of infection. The first influence which may affect the course of a syphilitic infection in the individual is presumably an intrinsic resistance or susceptibility to inoculation on the part of the host. On this point, while clinical evidence furnishes some presumption, it must be conceded that no positive statements are possible

Reported illustration exists of the exposure of individuals t virulent infection without subsequent inoculation, at least so far as such inoculation can be detected clinically On the other hand, it is now ell know that symptomless onset nd symptomless course ith unquestionable infection of the lymphatic system direct, even through an unabraded mucosal surface is possible in the rabbit and is, of course, by no means inconceivable for man. Brandt, in an extended study of syphilis in prostitutes, has the impression that an actual resistance t infection may exist and that omen ho do not acquire the disease early in their career subsequently escape it entirely Legram and Schulmann have published examples of what ppears t be outright, if only temporary immunity against virulent risk of infection. Metchnikoff and Roux reversed the logical process by showing that susceptibility mong the pes increases as one ascends the evolutionary scale and decreases in the lower orders.

The influence of resistance of the host on the actual course of a syphilitic infection after inoculation is likewise made difficult to define because it is unavoidably entangled with the problem of strain, of elective localization of the influence of the rate of reproduction of the organism at the time of inoculation of till unknown factors affecting its distribution through the body of the site of inoculation, as Brown and Pearce have demonstrated in the rabbit, and other influences a yet undetermined

Reference ha already been made t relative and variable resistance within susceptible group, as in the case of rabbits, here young animals undoubtedly offer the highest proportion

of "takes." Seasonal and dietetic factors have been recognized by Brown and Pearce and by Greenbaum, by Sulzberger and others, the summer months and green fodder apparently protecting, to some extent, against inoculation. Sunlight has also been shown by Brown and Pearce to influence the course of the disease in laboratory animals. Pearce and Van Allen found that in partially thyroidectomized rabbits, syphilitic infection tended to run milder course than in totally thyroidectomized animals. Pearce has also shown that rabbit inoculated in the testicle with syphilis and at the same time in the skin with vaccinia develop severe syphilis, but rabbits immunized t vaccinia as well as those inoculated intratesticularly with both vaccinia and syphilis develop milder disease.

So far as man is concerned the influence of race sex and pregnancy will subsequently be more fully discussed. Notwithstanding some suggestions to the contrary there is as yet no convincing evidence that in man, inoculation around the head or face or on the mucosa of the upper respiratory tract or inoculation directly into the blood stream by transfusion significantly modifies the general course and manifestations of the disease. (See however Pian and Framer "Transfusion Syphilis" 1040)

Vascular and Lymphatic Localization of Spirochaeta Pallida.—One of the most obvious localizations of the organism has probably escaped more emphasis because of its universality—namely that to the vascular system. While of course undoubtedly influenced by the mode of distribution of the organism through the blood stream the tremendous importance of syphilis of the blood vessels in every phase of the disease as a whole points as strongly as any single piece of clinical evidence toward a distinct vasculotropism Olsen (1938) summarizing Warthin s, Starry s and his own studies of the morphology of *Spirochaeta pallida* described a distinctive "small form in addition to typical spirochetes, granular ringed and filamented forms, in late syphilis of the aorta.

The complications centering about vasculitis and perivasculitis from aorta to capillaries are legion, and have even been invoked by critical students of the pathology of the disease such as Brown, as quite sufficient explanation without reference t allergic phenomena for most of the late manifestations of the disease. In ordinary clinical experience one finds certain persons predisposed toward certain types of involvement in truly wholesale fashion, as in the patient in Fig. 801 whose bones seemed to be veritable target for his spirochetal invader or as in the patient in Fig 508, who developed a remarkable series of Charcot arthropathies with his tabetic neurosyphilis. While superficially at least these may be interpreted as differences due t susceptibility of the host structure there are too many other factors, such as accidents in initial distribution and peculiarities of the strain of organism involved, to permit of definite decision. The almost uniform occurrence of interstitial keratitis as complication of heredosyphilis may be an example of predisposition of tissue or t may be evidence of the effect of the mode of inoculation on the course of the disease

The tissues of the lymphatic system probably stand next to those of the vascular system in their susceptibility to inoculation and their activity as carriers of the infection In fact, the term lymphatic reservoir" is a tribute to this predisposition Moore (1930) points out the perfection of symbiotic relation between host and organism in the lymphatic system In the rabbit, the organisms persist there for the life of the animal but in man, according to Moore they tend to disappear The high virulence of lymph node material in which no spirochetes are recognizable by darkfield (Bessemans) should be remembered The influence of latency in changing the propagative and pathogenic properties of the *Spirochaeta pallida* has been touched upon by Engman and Eberson but has not elsewhere as yet received the study which its very great importance demands.

In studying the distribution of infectious recurrences as they occur in *relapsing early syphilis*, Besancon, Seboch and Stokes were impressed with the uniformity and high proportion of genital involvement in this particular type of lesion. Genital relapse so strikingly outnumbers all other types of relapsing cutaneous and mucosal lesions as t seem almost t constitute evidence of a distinct elective localization, if not tropism.

Infection through a Break or Abrasion.—Curiously enough, tradition has proved to be in error in one of its seemingly best established tenets with reference to the influence of trauma on inoculation with syphilis. The common belief that an abrasion or break in skin or mucous membrane is essential to the penetration of the *Spirochaeta pallida* into the tissues has been negated now by so much experimental evidence that it may be regarded as definitely disproved.

Neisser early pointed out that rupture of continuity if it existed, need do no more than give entrance t lymphatic radicle and need not of necessity involve blood vessel. The subsequent experiments of Brown and Pearce and Mahoney and Bryant (1934) have shown that inoculation even through the highly resistant vaginal mucosa of the rabbit takes place without any trauma whatever and that while no reaction may ppear at the site of entry involvement of the lymphatic system rapidly follows. In man, the appearance of the chancre at the site of inoculation is, of course, the expected sequel of the entry of the organism but there is much reason to suppose that the primary reaction may be absent and inoculation show its first signs, not at the point of traumatic entry but in the adjacent lymphatics (bubon d emblée) Infection of old and healing wounds has been reported in man, and a probable case of such an occurrence is shown in the case of a herniotomy wound in Fig. 290. Chesney showed the granulating wound in the rabbit t be specially reactive to inoculation.

Needle-prick (Surgical) Inoculation. Syphilis d'Emblée.—Traumatic inoculation by injuries incurred in the course of surgical operations such as needle pricks, is well established A distinctive and unfortunate feature particularly of the needle-prick inoculation is the asymptomatic character of the onset. The general group of asymptomatic onsets is spoken of as *syphilis d'emblée* a category which has been steadily reduced by critical examination of patients and records to discover an occult, inaccessible or trivial primary lesion. The onset of syphilis in the intra-urethral chancre is a particularly frequently overlooked lesion in supposed asymptomatic onset. Burbi differs from us in believing that transfusion syphilis runs a distinctive course.

Trauma in Syphilis. The Locus Minoris Resistentiae.—A broad definition of trauma to include not only injury but overstrain, would place traumatic influences among the principal factors in the localization and course of many aspects of syphilis. There is unfortunately an unexpected quality about the effect of trauma which may make it appear of small significance in an individual case Unquestionably the chief significance of trauma appears in the later periods of the disease

Cazenave is credited by Klauder bo has been the chief American student of the clinical side of this problem, with being the first t recognize traumatic influence in provoking syphilitic manifestations. Ricord mentions it and irritation as trauma in the form of tobacco, dirt and friction has long been regarded as cause of infectious recurrences in the mouth and around the genitalia. Development of lat syphilis in tattoo marks (fine example by Keidel) and palmar syphilis of laborers are recognized. T masz ky *cauterisatio provocatoria*, the production of gummas on the skins of syphilitic patients by caustic past proposed for diagnosis, remains unconfirmed at least with regard to the presence of *Spirochaeta pallida*, by Greenbaum and Madden study (1932) Experimentally the resistance of rabbits against reinfection with homologous strains can be broken down by injury as demonstrated by Chesney and Kemp Even with the homologous strain, against hich high degree of resistance is t he expected it was possible

I secure "takes" in 7 out of 16 rabbits as demonstrated by lymph node transfer though only one animal developed a chancre

Gumma in Surgical Scars.—Development of gummatous manifestations in the scars *of healing* wounds of surgical operations is known especially in operations involving the nasal septum and pharynx in heredosyphilis Goeckerman s general study of this problem as a factor in surgical recovery indicates that the large majority of surgical patients with syphilis may be operated upon with impunity from the standpoint of wound healing Scheffey has *recently confirmed* these observations and Wiltrakis and associates (1941) found the general surgical risks and mortality of syphilitic and nonsyphilitic groups very similar Nonetheless, it is evident that incision or trauma inflicted upon tissue that has already undergone gummatous change is a very different matter from operation on the normal tissues of a syphilitic patient The reaction of gummas that have been traumatized or operated on is immediate and disconcerting, a rapid and destructive extension and prolongation of the process being the almost invariable result. Numerous examples of gummatous changes in war wounds were recorded during World War I

Other Traumatic Complications.—Gumma of the testis occurs following trauma and delay or nonunion of fractures is also known to be at times due to gummatous changes. Klauder describes cases in which the Wassermann reaction became positive after trauma, although repeatedly negative before Landouzy s case of an army officer who, after twenty five years of latent syphilis, developed an osteitis following a fall from his horse is typical of a considerable group of reported observations. Tumpeer quotes Lacapere and Laurent, who observed fourteen gummas of the forehead in forty Moslems, due to trauma from the rubbing of the frontal bone while kneeling Moslem fashion, with the forehead against the stone floor of the mosque Injury to the head has long been thought to be the starting point of clinical manifestations of paresis in certain patients. After a critical examination of this question, Klauder and Solomon endorse Calvi s summary of the medicolegal status of the relation of trauma to dementia paralytica. This states in effect that trauma, while not an exclusive may be an occasional cause of dementia paralytica and that three types of cases may be distinguished in the first *of which the period of latency* and recovery *after the injury is too long* to permit a causative interpretation in the second symptoms of dementia appear immediately after the trauma and the injury itself is to be regarded as an aggravating but not a causative event and third a type in which the interval between dementia and injury is neither too short nor too long and previous mental health can be completely established Nonne (1940) believes that trauma as a precipitating cause of central nervous system syphilis, can be overemphasized as shown by the experience in severe head and spinal cord injury in syphilitics in the First World War Numerous case examples will appear in the material of subsequent chapters in this text and the wide variety of traumatic influence which, as Gougerot and Clara point out, may follow every type of injury mild or severe sudden or prolonged single or repeated will be illustrated.

Industrial Trauma and Syphilis.—An expanding interest in syphilis in industry brings out an increasing case literature on the importance of trauma in the syphilitic employee (Stokes Beerman and Ingraham 1938) Eliet,

by a vascular reaction which assumes the form of endothelial swelling with proliferation and development of an obliterative endarteritis. This is accompanied by perivascular infiltration with lymphocytes the appearance of plasma cells, and finally fibroblastic proliferation and healing Immediately following inva ion and during the phase of vascular and perivascular reaction, the spirochetes increase rapidly in numbers Penetration of the surrounding lymphatic channels and the escape of the rapidly reproducing invaders into the blood stream where they continue to reproduce, go on to an increasing extent. It was pointed out by Kolmer in 1920 and experimentally confirmed recently by Brandt that material from rapidly growing primary lesions gives rise to more rapidly growing chancres than those which develop when infective material is taken from a slow-growing lesion This would certainly argue that there is a species of dynamic drive involved in the reproductive rate of the *Spirochaeta pallida* and that a rapidly reproducing strain such as would be obtained from an infection acquired from early acute lesions may be capable of rapidly flooding the system as well as the local focus with organisms. At the height of its development the local focus, whether a chancre on the genitalia or a colony of spirochetes in the liver becomes a contributor to the systemic infection and to the local area of lymphatic infection to a degree proportional to its size and the reproductive activity of the parasites. Then a change takes place as the histologic signs of healing begin to appear Fragmentation of the spirochetes can be recognized, the number and viability of the organisms decline granular change in the spirochetes appears followed presumably by phagocytosis of the granules by the lymphocytes attracted to the scene of reaction. The focal infection begins to subside.

Significance of Local Healing.—If the reaction which inhibits and destroys the organisms in each local focus throughout the body in the period of secondary eruption for example could be persuaded completely to perform its duty immediate spontaneous cure would result in all patients and the clinical syphilologist would become extinct. Unfortunately the successive inoculations of adjacent and distant tissues produced by the multiplying penetrating and escaping spirochetes prolongs the disease almost indefinitely while the fact that structural healing does not necessarily mean sterilization, prepares the way for a certain percentage of local relapses. It cannot be too strongly stated that even though the activity of the surviving organisms at the site of a healing reaction may be temporarily suspended sooner or later in a considerable proportion of the foci, some degree of relapse occurs. The defensive mechanism which has developed loses its effect, the tissue immunity wears off and the reproduction of virulent organisms may be resumed followed by reinoculation of the local lymphatic area or even of the blood stream A fresh reaction in the newly infected tissues then begins and syphilis once more resumes its cycle of infection, reproduction, reaction, suppression and relapse.

Healing in a Syphilitic Lesion Is Therefore Never a Proof of Cure.—In fact, it is possible, by a selection of therapeutic methods to induce the healing of a syphilitic lesion without materially affecting its spirochetal content. Müller Kitchevatz, Pasini, Wechselmann and Arnheim E. Hoffmann Sandmann have confirmed and even proposed for diagnosis, the finding of *Spirochaeta pallida* in chancre scars.

Brown and Pearce, working, for example, with compound in the series prepared by Jacobs and Heidelberger arsenophenylglycyl-dichloro-amino-phenol, found that this drug suppresses the tissue reaction and produces immediate healing of the syphilitic chancre in the rabbit but

[illegible]

Fundamental Nature of Reaction. [illegible]

Relation of the Local Lesion or Chancre to Immunity and Defense.—The local lesion [illegible] many battles [illegible] struggle between [illegible] battle [illegible] character [illegible] integrity [illegible] reaction [illegible] local immunity reaction [illegible] to the reaction of the tissue and [illegible] reaction [illegible] or protection [illegible] through extension [illegible] ment and reaction [illegible] local immunity [illegible] it is also conceivable that the local lesion, especially if it be extensive, may not be important [illegible] but [illegible] a general mechanism of defense which [illegible] protect [illegible] even though they may not have been up to that time in the [illegible] history of the individual disease invaded by *Spirochaeta pallida* itself.

Thus the chancre in the rabbit, for example, [illegible] effect on the progress of the infection [illegible] in the text. One of [illegible] already mentioned [illegible] observed by Brown and Pearce [illegible] effect is that rabbit be amputated, immediate generalization of the infection [illegible] result. If the local tissue reaction be suppressed therapy [illegible] the infection, freed of the restraining influence exerted by the local reaction, disseminates through out the body in exactly the same [illegible] as if the chancre were [illegible] becomes apparent that the almost infinite number of local tissue reactions occurring in all parts of the infected animal or human body are the essential contributors to whatever general defense [illegible] the patient against such a disease as syphilis. T. Warthin particularly [illegible] the distinction of emphasizing to the pathologist and clinician the meaning of this local defense for the mechanism of latency to be presently mentioned. That the chancre reaction [illegible] in the initial infection

of man, has relatively unimportant controlling effect upon the fate of the syphilitic infection in his body as a whole is attributable, as Brown has pointed out, to the insignificant size of the lesion as compared with the mass of the whole body In the rabbit the scrotal chancre is the equivalent perhaps of several hundred human chancres in defense-producing capacity and for that reason it exerts much greater influence upon the course of the disease in the experimental animal than does the primary reaction in man. In fact, the reaction of the multiple foci in the human skin in the course of the secondary eruption is probably much more nearly comparable with that which occurs in the scrotal chancre of the rabbit.

As will presently appear then there is much evidence to support the belief that, so far as the individual himself is concerned multiple focal reactions in his skin in other words an extensive secondary eruption, permanently and favorably influences the subsequent course of his infection It must be emphasized here and repeatedly hereafter however that this form of individual protection has its weaknesses as well as its advantages and particularly from the standpoint of the public health in our present knowledge of the disease and of treatment must be to a large extent disregarded

Systemic Reactions.—Our knowledge of systemic or general reaction to a syphilitic infection in the experimental animal has not progressed so far as has our comprehension of the local reactive mechanism. Both clinical and experimental knowledge tends to support the importance of the lymphatic defense mechanism and its histopathologic background has been studied by Zurhelle Bergel Engman and Eberson, and most recently in man by Saleeby and Greenbaum and by Michelson The reticulo-endothelial system has been presumed to bear an important part in this mechanism but the suggestion of this influence comes rather by way of therapeutics than direct observation. The induction of reticulo-endothelial block by trypan blue and *Eisenzucker* has the effect of suspending the action particularly of arsenicals in the treatment of syphilis. The precise significance of this connection for the place of the reticulo-endothelial system in the spontaneous defense mechanism is not as yet clearly understood but there is little doubt the system plays an important part at times.

Organs and Structures Involved in Defense Reaction.—The importance of certain groups of tissues in defense against syphilis becomes more apparent when particular organs are considered. Brown and Pearce in particular have shown that the testis, the bones, the skin and the eye (Chesney differs) successively take up the protection of the body as whole and provide by their local reaction mechanism the source of much of the general physiologic defense. Observations of this sort substantiate the clinical tradition that human patients who have had extensive syphilis of the skin, bones and parenchymatous viscera such as the liver and spleen, usually escape the most serious forms of damage in the vascular and nervous systems, whose reactivity to infection is comparatively low and whose intrinsic defense is therefore weak.

Antibodies Agglutinins and Lysins.—The hope of finding a serum or vaccine cure for syphilis combined with the antigen antibody series in the mechanism of the Wassermann reaction has inspired a most thoroughgoing search on the part of many investigators both of man and animals for any signs of a general serological immunity reaction to the disease which might be utilized in treatment In general it may be said that every effort thus far made, based on the investigation of the properties of the blood serum of man and animals tested against virulent spirochetes from animal and human syphilitic lesions and against cultivated *Spirochaeta pallida*, has ended in failure In other words, the inference is that such general defense as exists against syphilis, resides in the tissues and in the cellular mechanism and is not present or distributed as a circulating substance or property

The ... literature on this subject may be followed in the summaries of Maher (Jadassohn Handbuch) and Chesney and Harrison (1931) ... Kast and Lynch (1941) and Kolmer (1942) bring the literature of the subject up to date. While it has been shown that agglutinins and lysins for *Spirochaeta pallida* are formed, the amount ... of ... effect on the disease is uncertain. ... enhance reducing properties on the blood serum of latency ... and ... Kahn ... theory ... the conclusion is ... that ... rather ... form of natural or stimulated immune ... reaction must be relied upon to control the individual infection.

Nonspecific Defense.—The systemic physiologic defense against syphilis has an element of nonspecificity probably imported into it by the multiple factors now so many times mentioned which must be borne in mind in interpreting the behavior of the disease under treatment. Not all of the effect of medication is on the spirochete itself and not all of the systemic effect of treatment is specific for syphilis. The action of foreign protein, of course, at once occurs to one as a fundamental example. The effect, however, may be observed even in medicaments whose action is supposed to be specific, such as that of the arsphenamine. Practically every drug used in the treatment of syphilis is capable of arousing a certain nonspecific and fixed element of defense which, while it acts on the syphilitic infection most markedly to be sure, is also capable of acting on tuberculosis and blastomycosis, for example. This nonspecific factor, repeatedly discussed in connection with treatment in subsequent chapters, is an important general ally in behalf of the patient.
Immunity relations and defense are revealed in reinfection, superinfection and cure in animals. It will serve the double purpose of clearly differentiating between what is known of syphilis in the animal and what is known of the same disease in man, if at this point we summarize the critical problems and conclusions in regard to these vital questions as they have been illuminated by animal experiment. The critical experimental question and one with wide sweep of practical significance, if the findings can be transferred to man, relates to the persistence of the *Spirochaeta pallida* as a necessary condition on immunity to reinfection. A positive or negative answer to this question would establish the position of reinfection as an absolute criterion of the complete extinction of every last spirochete in the animal body or of the establishment of an immunity or resistance to the disease intrinsic to the body itself and not dependent upon the continued presence of the organism. If it can be shown that every last spirochete can be extinguished and the animal yet remain for an indefinite or a limited period of time refractory to reinfection, reinfection ceases to be the proof of cure which it has been considered to be in the past. The gateway of hope for the complete extinction of the disease with more or less lasting immunity to it begins to open, provided the conclusions are transferable to man.

On this extremely important question, two distinct schools of thought exist. Neisser Kolle Frei, and Prigge have contended that resistance to reinfection is dependent on the persistence of the original infection. In other words, an animal which cannot be reinoculated is still infected. Chesney and Kemp Voegtlin and Dyer Uhlenhuth and Grossmann, Manteufel and Richter Worms, and Brown and Pearce on the other hand, have maintained that an actual resistance to reinfection develops independently of the mere persistence of spirochetes and that an animal may be apparently immune to second infection while coincidentally free from the first infection In the process of development of these opposing concepts, a variety of important facts have come to light as follows (1) Shortly after development of a primary lesion, a second primary lesion cannot be produced by reinoculation. This observation is of course familiar in man and is designated in the original Neisserian conception of anergy or resistance and is now more frequently spoken of as chancre immunity (2) this chancre immunity is dependent on a reaction of the tissues and not on the mere presence of the organism. (3) Inoculation in certain tissues (for example, the cornea) does not protect against inoculation in other sites (for example, the testis) but certain tissue inoculations have greater general protective value than others. Moreover (Chesney Wood and Kemp 1929) the tissues of the eye in the rabbit do not share to the extent that other body tissues do, in the immunity state induced by syphilitic infection (4) An animal may harbor a syphilitic infection without reacting to it (Manteufel and Richter for the rabbit and Kolle and Schlossberger for the mouse) (5) In rabbits made carriers of infection by intravenous inoculation, the lymph nodes are infected the rabbit, however may be reinoculated with the same strain of organism while carrying the original infection in the lymph nodes and may from the second inoculation, develop typical syphilomas of the testicle (scrotal chancres) (6) Reinoculation of the rabbit on the site of a previous testicular chancre by a homologous strain of *Spirochaeta pallida* may take place in a proportion of instances, decreasing as the age of the infection increases. A larger proportion can be infected with a heterologous than with a homologous strain late in the disease (more than ninety days after infection) (7) Nonappearance of clinical lesions in animals after reinoculation is not a proof of failure to reinfect. (8) Chancre immunity the resistance to the development of a new chancre on reinoculation, is perhaps similar in kind to the slowly developed later absolute immunity to reinfection, but is less in degree, so that with only chancre immunity the animal may be reinfected, as subsequently proved by inoculations made post mortem from its lymph nodes and viscera. (9) The development of the complete or highest degree of immunity to reinfection varies in time with different individual animals and may be late or early depending on their constitution. There are intermediate cases in which the reinoculated organisms may penetrate only so far as the adjacent lymph nodes, where the infection may then be suppressed, or they may remain sequestered at the site of the second inoculation. (10) Superinfection, that is, the engrafting of a second infection upon a first one still present in the body may take place in rabbits after subcurative doses of the arsphenamines. The original infection thus remains latent and the lesions of the superinfection may so precisely resemble those of the original infection that they cannot be distinguished from each other without knowledge of the chronological and localization factors (Brown and Pearce)

It would appear then that the complete suppression of a syphilitic infection in the rabbit by treatment can be accomplished, but that there may persist after this infection (for the views of the Chesney and Brown and Pearce group of investigators seem to be gradually getting the upper hand) an immunity to reinfection which makes it impossible to use reinfectibility as a test of the cure of the original infection. It would appear moreover and this is a matter of vital importance in human syphilis, that subcurative treatment may instead of extinguishing an animal infection, merely reduce it to latency and that the animal may then be superinfected and develop new lesions while the original infection reduced to latency by treatment, still persists in the tissues Reinfection, even in cured animals, can only take place in those cases in which the chancre immunity and subsequent resistance developed are imperfect or of short duration. This use of the term "reinfection" must, of course be sharply differentiated from superinfection.

Allergy Gumma, and the Mechanism of Malignant Syphilis.—Just as the term *anergy* means a refusal of the tissues to react against the *Spirochaeta*

pallida, the term "*Umstimmung*" (Neisser) roughly translated by "allergy" implies a hyperreactivity on the part of the tissues to a local focus of spirochetes. We have seen that the conventional mechanism of defense against the *Spirochaeta pallida* is essentially a chronic inflammatory one and that the organisms disappear from the local focus, resistance being established coincidentally with the process of healing fibrosis. This type of reaction is fundamentally characteristic of the early, the latent and many of the changes of the late aspects of the disease. In a certain proportion of subjects, however, an allergic or hypersensitive state supervenes upon infection usually late in the disease but occasionally and especially under the influence of treatment comparatively early in the infection. The allergy or hypersensitiveness so far as it can be at present interpreted seems in the animal at least to be a function of the individual host rather than of the strain of organism. It may be predisposed to by intercurrent influences. It is probably inadvisable to speak of allergy in this connection as a form of defense though there can be no doubt of its tremendous and in fact explosive efficiency in destroying the small numbers of organisms which arouse it at the local site. Yet the histopathologic architecture of gumma as this late allergic local type of reaction is called has much in common with the more chronic forms of earlier healing reaction as in lymph nodes for example (Michelson). Gumma or better gummatous infiltration is the characteristic reaction of the late syphilid in structures such as skin, bone and other organ groups involved in the systemic defense mechanism already described. As a matter of fact, the essential differences between the early and the late gummatous inflammatory reaction are simply three. Gumma, in contradistinction to early syphilitic lesions contains so few spirochetes that their presence as a rule can be recognized only by animal inoculation. Secondly proliferative changes, necrosis and giant cells form a much more conspicuous part of the gummatous infiltration than of the other type of reaction. Thirdly from the clinical side gummatous infiltration is far more destructive because of its penchant for necrosis than are the local focal reactions in early syphilis.

The vascular changes are essentially the same both early and late and tend to differ only in degree. It must be conceded that able investigators have recently considered it unnecessary to invoke an extrinsic allergic factor to explain the peculiarities of gummatous infiltration. They feel the changes can be sufficiently explained on the ground of chronic vascular degeneration which have so reduced the viability of the tissues that a small number of organisms can produce marked destructive effect. Recently Warthin and Wile in reporting a unique case of fulminating destructive early syphilis, were able to establish through their pathologic studies that the classical picture of high grade malignant syphilis, in this case at least, was produced by thrombosis and obliteration of the medium-sized vessels forming the apex of the vascular cone in the skin. It appears, therefore, so far as this case may be used as a general example that a vascular cause may be invoked as an explanation of a good deal of what has passed as gummatous change of destructive character in both early and late syphilis.

Moore following Chesney maintains that the symptomless nonreactive carrier or latent state may be regarded as the anergic "response" to *Sp. pallida*, while the gummatous reaction type is the allergic, and that twenty-five per cent each of clinical syphilitic infections tend toward these types, with the remainder fluctuating between. None of these conceptions harmonizes particularly with that usage of anergy and allergy in tuberculosis, in which the proliferative gumma-like sarcoidosis is thought of as anergic tuberculosis — a tuberculosis without immune reaction, the tubercle being the allergic or immune reaction.

In connection with the discussion of gumma, it is wise to point out that the older clinical concept of gumma as the sole characteristic lesion of tertiary

syphilis need careful reinterpretation Gumma is not necessarily a massive or tumor like affair but may take the form of diffuse or miliary lesions in which fibrosis supervenes with relative rapidity thus avoiding the huge destructive breakdowns which are familiar in the large tumor like lesions Thus a gummatous infiltration of the skin may have the delicacy of parchment, may never ulcerate and may give rise to only the faintest signs of atrophy instead of the extensive and conspicuous scarring which conform more closely to the older conceptions. A gumma may vary in size from a microscopical lesion in the wall of a cerebral artery to a tumor the size of a grapefruit in the body of the liver but the fundamental pathologic mechanism underlying both lesions is identical

Specific Allergy and Cutaneous Tests in Syphilis.—The practical disappearance of luetin and its modifications from clinical diagnostic practice seems to justify simply a reference to the discussion in the second edition of this work, of the experimental background and status of the various spirochete containing suspensions tissue emulsions and so forth which have been tried for the clinical diagnosis of syphilis. Because of their nonspecificity uncontrolled or uncontrollable factors in their composition and a rather large margin of error as well as limitations in usefulness in the late stages of syphilis, preparations of the "luetin" type have been withdrawn from the market. The light thrown on the immunity mechanism so far as *Umstimmung* is concerned, is essentially that of indicating that iodide is capable of inducing in the body a physical-chemical state resembling the "allergic" state of late syphilis. So far as its cutaneous manifestations go this state can be to some extent imitated by breaking down any protein in the body even to the patient's own skin It seems therefore not impossible that the tremendous lysis of spirochetal protein which takes place under the action of the local defense mechanism early in syphilis may in a proportion of cases, prepare the way for the destructive allergic manifestations of late syphilis. It is also possible that lysis of the patient's own tissues at various times in the disease may furnish the necessary background. Such an explanation unconfirmed though it is, assists in the comprehension of the effects of spirochete-destroying treatment insufficiently followed through, in bringing on the dangerous early "allergy" and precocious tertiarism seen in the inadequately treated patients of the arsphenamine era

PRACTICAL APPLICATION OF PATHOLOGIC PHYSIOLOGY AND IMMUNITY CONCEPTS TO SYPHILIS IN MAN

The need for the systematic use of and constant reference to the foregoing conceptions of the pathologic physiology of syphilis in clinical diagnosis and treatment, is well illustrated by the decade lag almost universal up to 1917 between the lessons taught by the laboratory and the practice of diagnosis and treatment in man. The long taught and rather artificial clinical classification of the manifestations of the disease into primary secondary tertiary and quarternary periods induced a false conception of island-like or isolated phenomena unconnected by a continuous or an undulatory fluctuating give-and-take of attack and defense. Latency long a sacred retiring ground for *Spirochaeta pallida* within the human organism has in more critical recent examination turned out to be nothing but a clinical make-shift conception in which the fundamental continuity of the attack-defense process is main

tained simply at a low threshold of visibility. The latent patient is simply one without obvious symptoms, and the appraisal of his status by increasingly searching means reveals less and less of him so to speak, than was previously conceived. The primary stage of the disease, long thought of as one of limitation of the infection to the immediate neighborhood of the chancre and adjacent lymph nodes, formed a basis for the protracted adherence to a mistaken therapeutic conception of "abortive cure." The German syphilologists who were the authors of the concept were themselves in the end the most emphatic in repudiating it. Relapse and recurrence, long submerged in clinical importance by inadequate clinical examination, inadequate use of the darkfield, inadequate serologic exploration, are now coming into their own as in many respects clinically the most threatening and significant aspect of syphilis as a public health problem. They were not even considered in the old serological classification. In order to condense into the briefest possible space the modern conception of parallelism between clinical picture and pathologic background, Figure 7 has been devised. In this résumé remnants of the old "stage" terminology appear which are used to link the syphilologic parlance of the clinic with the fundamental immunology and pathogenetic conceptions of today.

FIG. 6.

SOME IMMUNOLOGIC PRINCIPLES

1. A immunity to syphilitic infection in man, in first instance, is unproved, probably rare, and unconvincing rather than badly.]
2. Within a few weeks after infection, however, immunity against re- or superinfection develops, which probably persists indefinitely, perhaps throughout life.
3. For reinfection to occur the disease must apparently have been cured before immunity has developed.
4. A nonreactive carrier state, in which the organism, though present, provokes no reaction in the host, is recognized in animals and probably exists in man.
5. Removal of the infecting organisms in large numbers by spirocheticidal agents probably interferes with immunity development.
6. The source of the immune state seems to be largely the local (chancre or local type) tissue reaction. There is, however, a humoral (?) element of as yet undefined nature, extent and significance.
7. The excision of foci like the chancre or the scar has no protective value. It could not generalize the infection, by removal of a major source of local defense.
8. The participation of defense groups of structures (skin, lymph nodes, test...) accepted but undefined. The reticuloendothelial defense is hypothetical.
9. No outright phagocytosis has been observed.
10. A granular rest or cyst stage of the organism is suggested by histologic observation and some features of the immunity.
11. Vaccines are ineffective, even increase susceptibility.
12. The humoral antibody and the "Wassermann" reagin are distinguishable (Kolmer et al.) (indistinguishable (Eagle et al.)).
13. An allergic or hypersusceptibility element enters into the tissue reaction of late syphilis (Kast meaning).
14. Healing is not proof of cure. Virulent organisms may be found in lesion scars of early syphilis.

The unit in this type of defense is the microscopical group of lymphocytes and plasma cells which collect in an infiltrative reaction around the spirochetes lying in the lymph spaces adjacent to the capillary vessels. The reaction set up in the vessels in the form of endarteritis reduces the blood supply of part of the parenchyma with ensuing degeneration. The lymphocytic infiltra

tion following identically the course of the typical reaction t all stages of the disease is gradually replaced by fibroblasts and fibrosis of the local focus ith a further loss of parenchyma results. The end-result of this microscopical focal reaction is, therefore *degenerative* and replacement

Fig. 7

COMPARATIVE RÉSUMÉ OF THE CLINICAL COURSE AND PATHOLOGIC BACKGROUND OF SYPHILIS

Cl ical Picture	*Pathologic Background*
1 Inoculation and Primary Incubation Period.—N clinical signs of infection.	1 Reproduction of organism going on in perivascular lymph spaces, with rapid distribution t lymph nodes, blood, spleen, bone-marrow etc., within a few minutes (imals) to t t three days after inoculation.
2. Primary Stag —Chancre usually p-pears t inoculation sit but with wide variation in local reaction even to complet absence Local lymphadenitis (bubo). Systemic symptoms (headache bone pains, et) may appear in advance f outspoken lesions. Blood W ssermann nd precipitation reactions begin t become positive	2. Lymphocytic and plasma cell infiltration produces papule and induration. Reproduction of organisms in chancre i t it height. Other similar foci developing throughout the body their number location, and activity proportional t virulence of organism nd peculiarities of host. Spirochetes present i blood-stream.
3. Early Secondary Stage.—Chancre begins to heal and widely distributed secondary skin manifestations develop with lymphadenitis, enlargement of spleen, bone lesions, changes in the nervous system, etc. Special structures may be ttacked, as eye, ear liver kidney ith serious results. Refractory stat develops, ith positive blood Wassermann nd precipitation reactions. Average infection up t second year	3. Local immunity reaction begins t destroy spirochetes in chancre and earlier secondary foci in viscera, as healing sets in. Enormous number of new foci established in skin, bones, lymphatics, viscera, etc. Systemic defence mechanism of agglutinins, lysins, etc., comes int play Lymphocytes disappear from healing foci, fibrosis occurs, organisms may be completely or partially destroyed or suppressed Foci in all stages of activity and decline throughout most of the body spirochetes numerous in blood-stream, innumerable minute spirochetal rests established in pericapillary lymphatics with larger probably temporary reservoirs in lymph-nodes.
4. Late Secondary Stage.—Secondary eruption disappears spontaneously systemic manifestations subside. Some symptoms from local foci may persist, such as palpable spleen or liver active but asymptomatic neurosyphilis, et Second to third year	4. Enormous destruction of spirochetes throughout the body complete in some foci, partial in others, the latter providing basis for relapse. Spirochetes become fewer or disappear from blood-stream with occasional showers. Systemic resistance mechanism reaches highest development toward end of this period, leading t latency
5 Early Recurrent Stage.—Any lesion of the primary and secondary period may reappear but especially lesions on mucous surfaces. Primary lesion and secondary eruption may reappear if temporarily aborted by treatment. Second to sixth year	5. Defects in local resistance with revival of partially extinguished foci and new showers of spirochetes with new crops of lesions developing from them.

Fig. 7 (Continued)

Clinical Picture	*Pathologic Background*
6 **Latent and Late Recurrent Stage.** Prolonged absence of symptoms, or periods of relative quiescence punctuated by relapses with lesions in bone, skin, mucous membranes especially. Lesions become fewer in number due to scarcity of spirochetes and more localized and destructive in habit, [illegible] due to developing allergy and vascular changes. Fourth to tenth year or later. **Note the overlapping time relations, in which almost anything may be expected at any time.**	6 **Spirochetes much diminished in number** and held in suppression or commensalism by local and general resistance, by immune and local defence at its highest development or by *nergy* (Chesney, Moore) tissue nonreactiveness. Local lesions may still flare up, however, discharging [illegible] organisms into circulation or lymphatic drainage area, starting new crops of lesions in susceptible tissue or reviving old ones. Patient may be rendered temporarily infectious to contact, or fetus may be infected, for example. Chronic inflammatory defence active, commensalism [illegible] foci may [illegible] strong general immunity but resulting in degenerative changes and fibrosis. Patient "living on his parenchyma."
7 **Late Syphilis, Gummatous Phase (Tertiary Syphilis).** Tumor-like lymphocytic and granulomatous masses appear in various organs. Central necrosis from endarteritic ischemia, extensive sloughs, much destruction of parenchyma and scarring. Lesions not usually infectious.	7 **Development of allergic (?) hypersusceptibility or effect of chronic vascular changes.** Violent tissue reaction to small number of organisms. Spirochetes in the lesions few and far between. Cutaneous allergy of nonspecific type demonstrable in many cases.
8 **Late Syphilis, Degenerative Phase (Quaternary Syphilis or Parasyphilis).** Degenerative lesions of cardiovascular and nervous system. Fibroses of parenchymatous structures, such as liver, spleen, pancreas, etc. Clinical changes and fatal result due to loss of parenchyma replaced by fibrous tissue [illegible] the blood supply [illegible]	8 **Spirochetes present,** at times numerous in some structures, but usually only to be found by special search of microscopic foci of tissue reaction in aorta, heart muscle, viscera, etc. Blood serologic reaction may be negative. Result: fibrosis, ischemia, necrosis.

of functionally active parenchymatous tissue [illegible] inert and weakened scar tissue takes place. These individual reactions and foci are almost infinitely numerous. They occur throughout the capillary distribution in the parenchyma of all the important viscera, in the heart muscle, around the vasa vasorum, in the [illegible] of the arteries, and in the nervous system. Their slow combined inflammatory degeneration ages the patient by inducing premature fibroses, and impairs the functional capacity of his vital structures by destroying their very substance and replacing it with connective tissue. The course or life history of these individual foci, varying between the extremes of healing and of rapid reproduction of organisms with distribution to the blood stream and lymphatic system at various periods throughout life, has been described. It is apparent in clinical experience that the tendency for such revival to occur with their ensuing relapses probably decreases considerably with the passing years. That it may, however, be [illegible] of relatively long latency is indicated by the reappearance of infectious lesions more than [illegible] decades after the onset of syphilis in patients who, in the interim, have remained entirely clear. The infection of the child in utero, the mother with latent syphilitic infection of a number of years standing, is also conceivably explainable through a transient spirochetemia associated with the revival of several latent foci.

Relapse is more prone to occur in man than in animals (Brown and Pearce) and is a function of decline in local tissue resistance which, however

is gradually enhanced by repeated increments in successive relapses until it becomes sufficient to hold the infection in check for a latent period varying in duration with the individual and with other factors such as injury While this resistance to multiplication of the organism and spread of the infection from any local focus is sufficient when highly developed to prevent clinical manifestations, the infection is not abolished but continues in a high proportion of cases indefinitely

In reasoning about the immunity developed in the later years of syphilitic infection, it should be clearly understood that its duration and the influence of individual constitutional factors are as yet imperfectly understood even for the animal, to say nothing of man. It is conceivable, and in fact the belief is to some extent supported by the work of Breinl and Wagner that there may be infected persons who develop only partial immunity such as the chancre immunity; that others may develop a complete immunity of less than lifetime duration and hence in later years may become susceptible to reinfection or more probably to superinfection, and that some persons may though rarely develop even chancre immunity of short duration and may as apparently chronic relapsers, be, in reality chronic superinfectors.

The clinical manifestations of relapse are of course legion and are essentially those attributable to the activities of the disease in the structures involved In the nervous system, relapse may be general or extensive or it may be so localized that there is no recognizable general meningeal or serologic response. Relapse may conceivably be fulminating and involve an entire organ mass, such as that of the liver in a colossal destructive revival of the infection. Relapse may be serologic in the recurrence of syphilitic reagin in the blood or spinal fluid, with or without clue as to the active focus from which the laboratory manifestations come. Relapse varies in type with the type of lesion of the phase of the infection, chronologically or otherwise present at the time. Thus, wholesale outbreaks of tertiary lesions may occur in late syphilis or they may equally well occur in early syphilis into which late "allergic" characteristics have been introduced by one or another circumstance. Infectious relapse is, of course a matter of great clinical and public health concern, and since it is largely manifested on the mucocutaneous surfaces and junction points, it is spoken of as mucocutaneous relapse. It is overwhelmingly an incident of the first two years of syphilitic infection in man but the more closely one explores supposed clinical latency in the first ten years of the disease, the more to his surprise does he encounter the isolated infectious relapse as a source of dissemination of the disease. The clinical characteristics of infectious relapse in man are especially considered in Chapter XIII and reinfection, which is often confused with relapse when it occurs within two years after the onset of a syphilitic infection is also subsequently discussed (Chapter XIII)

Treatment and the Mechanism of Relapse.—Treatment of less than curative intensity reinforces or operates through the bodily defense at any given point, destroying the multiplying organisms and permitting healing and disappearance of lesions On the other hand, it must be clearly understood that no treatment at present available is able invariably to prevent either the later reappearance of the original lesion or the further development of new ones when the relapse cycle permits the organism to resume multiplication and to overwhelm the tissue defense The deficiencies of short courses or scattered injections of the arsphenamines are notable in this regard. Relapse is particularly to be expected in patients treated with these drugs in subcurative doses, without proper reinforcement by the heavy metals.

Beckh, Barnett and Kulchar (1933) in summing the question, gave an interesting clinical review with reference to relatively small group of patients, indicating that the simultaneous use of arsphenamine and heavy metal, inadequate dosage of the arsphenamine either alone or feature of the so-called "continuous" treatment, contributed to treatment refractoriness, failed to control relapse, and increased the frequency of relapse in patients who became treatment-resistant because of the system employed. It should be understood that combined treatment here means simultaneous use of the arsenical and heavy metal and not alternation.

Relapse is critical if it involves a reviving focus in an important and poorly defended group of structures such as the nervous system. It follows therefore that a small focus of spirochetes in the meninges adjacent, for example, to the nucleus and trunk of the eighth cranial nerve can, upon their revival in the course of relapse, give rise to a fulminating and critical damage out of all proportion to the significance of the focus in the general display of reaction during the early months of the disease. The inadequate use of an arsphenamine in primary syphilis before the development of secondary lesions may thus, because of its interference with the development of the bodily defense, pave the way for a critical relapse dependent upon the location of the relapsing focus. Relapse tends to become malignant when it follows *insufficient allergy-inducing treatment* with the arsphenamines, which is rapidly destructive of large numbers of *Spirochaeta pallida* in the tissues and circulation. It was intimated in discussion of luetin that such a proteolysis seems to have in a certain proportion of subjects a tissue-allergy inducing effect. Thus when the inevitable revival of scattered foci following inadequate treatment occurs, each focus finds itself reproducing in an allergically reacting soil. The result is the appearance within a few months or even weeks of the primary infection of lesions highly destructive and fundamentally tertiary in character, dependent upon the premature induction of *Umstimmung* by treatment. Thus cerebral gumma, fulminating and fatal hepatorecurrences, destructive gummatous changes in bone and skin may be the result of treatment-induced allergy. This type of recurrence should be distinguished at least to some degree from the critical relapses whose anatomical location rather than their intrinsic destructiveness is responsible for the importance of the clinical symptoms. The differentiation, however, is theoretical rather than practical.

Is There a Relapsing Type of Human Syphilis?—It appears that the clinical conception proceeding from the opposition in the early arsphenamine days that an abortive and spirochete-destroying type of treatment by preventing a "healthy reaction" in the form of the full development of the secondary cutaneous eruption impairs the resistance of the individual to the disease is not without support. From studies in relapse it appears that the full secondary reaction exerts some inhibitive effect upon recurrence and that patients whose infection has been allowed a complete generalization and whose blood serological tests have become positive are distinctly less subject to relapse than are those on whom treatment is begun at an earlier stage. From still further studies it appears that there is in man a definite type of chronic relapser who, in accordance with the conception of Breinl and Wagner, never develops more than a partial immunity, or if he does develop it, does so only at the expense of so many relapses as to make him a constant and significant danger to the public health. These considerations are further discussed in Chapter XIII.

The actual figures in this matter (Cooperative Clinical Group) are as follows: Relapses were observed in 64 or 10 per cent of 810 patients with seronegative primary syphilis; in 105 or 8.8 per cent of 1203 patients with seropositive primary syphilis; and in only 4.16 per cent of 3930 of those patients admitted with florid secondary syphilis in the first year of their disease. Thus it would seem that the gradually developing resistance of the patient to the infection cuts the proportion of relapses 58 per cent from the maximum observed in seronegative primary cases as the patient passes to the eruptive secondary stage occurring within the first year of the infection. Of 121 patients who failed to develop secondary lesions until after the first year of the disease, a large proportion developed relapse (22.31 per cent). Mucocutaneous relapse is therefore twice as likely to occur in patients who developed delayed secondary lesions as in the seronegative primary case and more than five times as likely to occur as in the patient who develops normal early eruptive reaction. Studies by the group of the relative efficacy of treatment in seronegative and seropositive primary syphilis compared with secondary syphilis further indicate that the development of secondaries reduces the tendency to relapse.

THE PROBLEMS OF REINFECTION SUPERINFECTION AND CURE

The question of the cure of the disease in man as demonstrated by animal inoculation methods is therefore still *sub judice* and unlikely to reach determination within the next half century if not longer lacking investigation of fresh autopsy material under proper conditions of cold preservation and shipment to experimental centers. The evidence collected by Lake and Bryant and a brief paper by Chesney indicate that methods of determining cure in man have fundamental and serious uncertainties. "But why not accept reinfection as the proof of cure?" is the insistent question of the average syphilologist and clinician. It is experimentally demonstrable that much that would appear to be reinfection in animals is merely superinfection or a second infection engrafted on one which has reached the stage of asymptomatic latency. The alteration of immunity relations by treatment both in man and animals and particularly by incomplete or substerilizing treatment with arsphenamine may so distort the clinical picture that relapse reinfection and superinfection become indistinguishable from each other. Recent contributions on this subject include Kopp and Solomon (1939), Hahn (1941) and Allison (1942) (reinfection in congenital syphilis).

Syphilis binaria [illegible] (Hoffmann) is syphilis inoculated in birth upon an infant already rendered congenitally syphilitic by infection in utero.

Superinfection in Man.—Superinfection with generalization from an inoculation focus and the production of typical primary and secondary lesions with recovery of *Spirochaeta pallida*, has long been in doubt in man. If the work of Japanese investigators, including that of Akatsu, Yakota, Adachi and Hashimoto, is confirmed, superinfection following a course indistinguishable from reinfection or relapse will become an established entity in syphilis in man. Alleged reinfections occurring soon after the original infection will then be interpretable as relapses while those occurring years after the original infection when general immunity has perhaps begun to decline, will be interpretable as superinfections. This will inevitably mean that the final demonstration of cure in man will be forced back upon the studies of pathologic tissue and inoculation of human tissues into animals which must remain the province of the postmortem room and the laboratory inasmuch as they are obviously inapplicable during life. We may in a pessimistic mood regard ourselves as fortunate if syphilis-infected man is not proved to be, at once the world's most uncontrolled and uncontrollable relapser its most chronic

superinfector and is perhaps the most perfectly adapted asymptomatic carrier in nature

COLLATERAL INFLUENCES ON THE COURSE OF SYPHILIS

These for brevity are summarized from experience and the literature as follows

1 **The Organism** strain rate of reproductive activity route of inoculation site of inoculation size of inoculum

2 **Season Sunlight** ultraviolet (Harnes) hibernation (Jahnel) Experimental animal only

3 **Endocrine Hormones and Activity** (thyroid Pearce) theelin castration testosterone in experimental animal (Frazier and Hu 1941 Hu 1939 Kemp et al 1939)

4 **Diet** sunlight and summer feeding in animal only ((reenbaum) Earlier development of lesion in acid vs in rabbit (Nagai Ogata 1938-39)

5 **Avitaminosis** A and B in tabes (Moore and W)) B_2 in interstitial keratitis (Kruse Sydenstricker Sebrell and Cleckley 1940)

6 **Defense Mechanism** bone and skin involvement (Brown and Pearce Shaw) reticuloendothelial (elasmatic) activity lecithin injection etc (Morgan and Cunningham et al 1933 1934)

Age childhood mucosal syphilis especially frequent (Jean) more profound tissue reaction early syphilis mild course (Jean Morgan Smith in man Chesney in rabbit) Neurosyphilis more treatable (arsenic excretion spinal fluid Clausen and Jean Old age more florid early lesions.

8 **Race Negro** (Turner Johns Hopkins 1930 Hazen 1930) *Secondary syphilis* marked polyadenitis, frequent follicular and pustular syphilis, almost a monopoly of annular syphilids Negro female conspicuously predisposed to mucosal relapse *Late syphilis*—bone lesion exceed *neurosyphilis* latter only half as frequent as in white patient (30.5 vs 15.0 per cent females 22.5 vs 0 per cent) *Cardiovascular syphilis* twice as frequent as in whites *Leuk pl kia rare gumma f lymph nod* frequent *cerebral e darteritis* cerebrospinal syphilis as frequent as in whites tabes and paresis rare **African Negro** (MacArthur 1923 no visceral syphilis no miscarriages **Central American Indian** little visceral syphilis Shattuck **Arab** little neurosyphilis (Lacapere Bejel a special mild non venereal type (Hudson 1938) **Chinese** tabes and *paresis rare* (*Jeffrey and Maxwell*) *no spirochetes in spinal* fluid (Pearce Hu and Mu 1930) **Japanese** European incidence of tabes and paresis **Icelanders**, no syphilis For extensive review see Buschke and Joseph Jadassohn Handbuch **Animals**, see Rosahn 1933 Frazier and Mu 1930

9 **Sex** milder in women to the point of being almost a distinctive disease (Warthin 1928) probably due to biochemistry of menstruation and pregnancy comparable to nonspecific or shock therapy (Petersen and Hecht, cited by Becker and Obermayer 1940) immunity of heart aorta nervous system ovaries predominant though infrequent lesions of liver pancreas suprarenals. Repression of surface eruptive lesion more frequent constitutional symptoms tendency to lymphocytosis Lessened susceptibility to neurosyphilis 30 per cent (Stokes) to 50 per cent (Moore and Keidel) *Sex hormone*—estrinization of males produces milder course (Frazier and Hu 1941) Theelin same effect both male and female rabbit (Kemp Shaw and Fitzgerald 1939) Ovariectomy increases severity in females (Hu 1939) reversing Kemp and Shaw 1938

10 Pregnancy favorable influence on the course of syphilis first described by Hutchinson proven by statistical clinical studies by Moore (1922–23) by the Cooperative Clinical Group (Cole spokesman 1931) by Solomon (1920) and by Kemp and Menninger (1936) The course of early (secondary) syphilis is milder or suppressed in half the cases if infection occurs during pregnancy Secondary syphilis may be prolonged or the reverse (precocious tertiarism) may occur *Pregnancy prolongs latency over years may even lead to spontaneous cure* The skin, bones and nervous system are protected cardiovascular and visceral lesions more common. The syphilitic reagin fluctuates markedly in the blood and reversals to negative may occur spontaneously following delivery Ten per cent negatives may occur in florid secondary syphilis *Neurosyphilis is 3 times as frequent in males as females* though the incidence of abnormal spinal fluids early in the disease is the same in both Belote (1927) differed from Moore perhaps because of differences in approach and material (Moore had more colored patients though he subsequently proved this made no difference) Solomon found 44 per cent of women with tabes and paresis were nulliparae while of syphilitic women without neurosyphilis only 20 per cent were nulliparous The CCG showed relapse and progression to be nearly twice as frequent in non-pregnant as in women pregnant after acquiring the disease (7 per cent versus 4 per cent) The protective effect is more striking in Negro than white women. Kemp and Menninger found that coincidence of infection and pregnancy increased neurosyphilis, pregnancy in the sixth month to third year of infection greatly decreased it, with less beneficial effect if pregnancy did not occur until after the third year of infection. In late syphilis generally the CCG found the protective effect of pregnancy less marked or negligible

The animal experimental background (rabbits) has been established by Brown and Pearce (1920) and Chesney (1923) and Kemp (1937) "Pregnancy is good for syphilis but syphilis is *not* good for pregnancy "

11 Intercurrent Infection.—Broadly speaking, intercurrent infections acute, chronic, focal and general affect unfavorably the course of syphilis and its treatment.

Experimental Background Pearce 1928—vaccinia (virus infection) violently disturbs the immunity reaction and increases the severity of syphilis in rabbits Chesney Turner and Halley 1928—localization and development of syphilis lesions in granulating wounds and nonspecific inflammations.

Clinical Experience acute (especially epizootic) *virus infections* of nasorespiratory tract, and *influenza* affect *especially unfavorably* the course of neurosyphilis (particularly tabes) Responsible for treatment reactions especially dermatitis Pneumonia (lobar) may precipitate syphilitic pulmonary infiltration *Chronic infections* less clearly defined action largely debilitating, as in chronically infected Charcot joints, gall bladder disease renal irritability Chronic colitis maintains tabetic pains, etc. Hepatic infections interrelated with hepatitis and jaundice (catarrhal?) in syphilis and syphilis treatment. *Focal infections* notably teeth tonsils (Duke) maintain tabetic pains crises, retard healing of gummas osteomyelitis *Pyelitis* exaggerates tabetic symptoms though high fever may have nonspecific value *Malaria* may be followed by gummas of skin bones, interstitial keratitis *Biotropism*, Milian s term includes the ability of treatment for syphilis (especially arsenical) to flare nonspecific infections (streptococcal etc.) *Tuberculosis* disputed field usually affects the course of syphilis in various

ways Increased resistance to syphilis (Ohnawa 1022) Aronson and Meranze (1938) found that untreated syphilitic rabbits react differently than normal rabbits to intracutaneous injection of tubercle bacilli In 1940 they noted that local experimental tuberculosis pursue identical course in untreated syphilitic rabbits and in rabbits treated with treponemicidal dose of arsphenamine Evidence in man inconclusive so far Treatment for syphilis especially arsenical has marked nonspecific effect on some form of tuberculosis (not pulmonary) see Chapter V May also precipitate or activate latent tuberculosis (Padget and Moore 1930)

12 Heat, Fever (See also the discussion concerning the thermal death point of *Sp rockaeta pallida* see page 10) Heinman (1020) found chancres in rabbits healed and infection cured by tissue temperature of 104 F for 2 hours 107 0° F for one hour These observation are sufficiently confirmable in man (literature reviewed by Simpson W M, 1936) to justify rating elevation of tissue temperature by heat or fever from whatever cause or source as favorably influencing the course of syphilis at all stages Not all the effect is attributable to the temperature as such for surface lesion which do not reach such temperatures are sterilized nonetheless Lymph node spirochetes more resistant than chancre spirochetes (Boak Carpenter and Warren) Certain infection like malaria may produce paradoxically complication like interstitial keratitis probably for immunologic or allergic reason independent of the effect of temperature Morgan minimizes thermal effect as such in surface lesion rating other systemic effect of fever probably more important

13 Physical Strain – As distinguished from the effects of trauma, predisposing effect of overwork is best seen in increased frequency of cardiovascular syphilis in those doing hard muscular work (Cochem and Kemp 1937 also Lerkel 1930 Farmer found aortitis 11 4 per cent in medium and heavy occupation 8 per cent in light occupation aneurysm four times as frequently in heavy as in light work insufficiency three times as frequent in heavy as light work. MacArthur (1023) found rest and feeding alone sufficient to heal many lesion in African Negroes Therapeutically while there are many variants, rest is an invaluable adjunct in dealing with syphilis.

14 Nervous and Mental Activity —Largely clinical impression that paresis affects more often person of sensitive and labile temperament subject to heavy nervous strains (e g physician executives, etc) that neurosyphilis becomes symptomatic (especially tabes) after nervous and mental stress Possibility that the psychic stress occasioned by the social implication of the disease may affect its course responses and apparent symptomatology suggested by Pearson (1031)

15 Physical Constitution.—A yet relatively unstudied in man Brown and Pearce (1023) showed that constitutional peculiarities in litters of rabbits influenced the course of infection Fleming and Moore (1041) review the literature and propose and detail an investigative plan Lerkel found 67 5 per cent patients with aortitis of pyknic habitus (Kretschmer classification) Lazarovits (1032) confirming Tabes more severe in asthenic (slender) types (Curtius Schletter and Scholtz 1038)

16 Trauma.—Previously considered

17 Treatment More completely considered under prognosis Chapter V Summarized no treatment or very little treatment lead to spontaneous inactivity or arrest in an as yet undetermined (see discussion of Bruusgaard

statistics) proportion ranging between 25 and 35 per cent of cases (Chesney Morgan 1930 Stokes and DesBrisay 1924) Inadequate use of heavy metal with arsenical or inadequate arsenical alone predisposes to neurorelapse Precocious tertiarism may follow inadequate arsenical therapy Inadequate dosage may establish relapse tendencies and treatment resistance (Beerman, 1930) Small doses may establish hypersusceptibility to the infection (Bronfenbrenner and Schlesinger 1920 denied by Schamberg 1940) Inadequate treatment may slightly reduce adequate treatment markedly reduces the frequency of neurosyphilis (Kemp and Menninger 1936) All treatment reduces the frequency of neurosyphilis and the seriousness of neurosyphilis and cardiovascular syphilis (extensive review by Harrison, L. W 1940-Venereal Disease and Life Assurance—including summaries of Cooperative Clinical Group results)

CHAPTER II

THE CLINICAL APPROACH TO SYPHILIS

Obstacles to the Recognition of Syphilis.—Foremost as an obstacle to the recognition of syphilis during the period covered by our experience has been a low index of suspicion among medical men. Next in order comes the substitution of subjective considerations for the objective approach of thoroughgoing impartial examination. Subjective considerations include those personal to the physician, such as his estimate of the social status of his patient, prejudices regarding the moral significance of syphilis, and hesitation when it comes to involving himself in an intimate and personal issue with his patient on a supposedly venereal subject. It also includes the even more important subservience to the patient's subjective misconsideration of his chief complaint and history. Its also on and denial which mark the history-taking approach to diagnosis. As contributory to some of the current weaknesses of our clinical approach to syphilis, one should include a tendency to wait for signs dependent on consequences in our diagnosis rather than to seek out in prophylactic fashion the earliest inconspicuous warnings of the presence of the latent disease. One should also emphasize the loss of respect for clinical as compared with laboratory evidence and the substitution of routinized tests for critical thinking which has marked the medical practice of the first years of the twentieth century. Finally, it is necessary to point out the weaknesses of a single method of approach to the disease and the necessity for attacking it from a number of diagnostic angles simultaneously if the highest possible accuracy in diagnosis is to be attained.

Suspiciousness of Mind.—Alert suspiciousness of mind, necessary though it may be in all medical diagnosis, is an absolute prerequisite to the successful detection of syphilis. This does not mean a mere vague awareness of its existence, such as an adequate training may substitute for definite knowledge. It means a sharp positive consciousness of the imminent possibility of encountering it, an alert sense of nearness such as is experienced by the hunter stalking big and dangerous game. A zest in the ferreting out of the obscure, a positively detective zeal in the running to earth of this most subtle master of the dissembling art, is the foremost asset of the clinical syphilologist. That this ultrasuspiciousness has its drawbacks is conceded, and they will be considered later. On the other hand, the physician who has a psychical blind spot for the disease sustains a life handicap as a diagnostician.

Alertness toward syphilis is effective only when it is chronic and consistent. The disease takes constant advantage of that type of diagnostician in any field whose search for it as a factor in his work is confined to occasional shake-ups following a report that some colleague more alert than himself has checked up one of his cases and by identifying the unsuspected syphilitic factor and by applying treatment has scored a triumph. Such an experience yields only a portion of its teaching value if the losing side is merely inspired to add another element to its routine procedure, as distinguished from its mental attitude—such, for example, as a Wassermann test on all patients showing edema of the nasal mucosa, or bilateral hydrarthrosis, or what-not. Valuable as some routine procedures are, failure to recognize syphilis in a given instance should lead the modern physician to do more than blindly enslave himself still further to any single routine aid. It should inspire him to re-canvass and furbish up his clinical acquaintance with the disease.

Low Visibility and Wide Dispersion.—*A low index of alertness or suspiciousness toward syphilis is* in the existing situation of the profession, a natural consequence rather than a fault. Syphilis is a disease of low visibility and wide dispersion of manifestations. A large part of its course is run below the threshold of attention. It has two relatively obtrusive periods, that of the primary sore and secondary eruption and that of terminal complications. In the former phase only half (55 per cent) of the diagnoses are made.

With the growing realization that the disease is often anything but obtrusive even during these outspoken periods of its course, it has become evident that in syphilis the physician has to deal with an almost unique diagnostic problem. Cause and effect, when the former is not entirely concealed, are often separated from each other by years and even decades of symptomless and signless latency, during which only routine probings with diagnostic tests and the most vigilant search for marks on a seemingly flawless surface enable us to detect the underlying pathologic process.

The nature of syphilis as a disease, then, has been a principal cause of lack of suspiciousness among diagnosticians.

Subjective Considerations.—*To the critical judgment, syphilis has of* course its moral phase, precisely as it has an ethical, an economic, and a social phase. But the effort to mix the standards of moral judgment with the medical issues of detection and treatment of the disease seems to lead to nothing but befuddlement.

One sees seriocomic instances in which capable clinicians betray the tenor of their thought by a sort of unconscious standard of reference, in which one Wassermann test will convict a laborer over his own denial, two will make a case against a banker or a railroad president, but three successive positives will scarcely convince the medical advisor of the guilt of a clergyman. The thin veneer of appearances, the air of prosperity, the evidence of education, an unimpeachable ancestry or the appeal of innocence constantly deprive patients of even the elementary investigation of the etiologic possibility of syphilis, to which, when rightly thought of, they are absolutely entitled. *So long as an investigation for syphilis appeals to any group of medical men as an affront, syphilis will elude their vigilance.*

The Nuisance of Syphilis.—There can be no doubt that to find syphilis at *the root of a diagnostic problem spells work, annoyance, and embarrassment.* The stigmatization of the disease by social tradition reflects itself in our search for it in patients. Even an experienced syphilologist finds himself at times puzzled to devise a tactful approach in a given case. If an experienced searcher meets such difficulties, *how often will the inexperienced be rendered lukewarm or actually deterred.*

The tradition of taking a venereal history is now well established, but the act itself is often superficial. *Unpleasant explanations may follow on the heels of positive findings in many cases.* The modern obligation to ferret out the ramifications of the disease in the family when it has been found in any one member is an added complication that discourages a too eager search. If the disease is found, there comes treatment with its complex modern standards, with which too few physicians can profess even a measure of confident familiarity. It is no wonder that a sort *of syphilological [illegible] or [illegible] comes to affect some of us after a few experiences with the* nuisance of syphilis in a diagnostic complex.

Overemphasis and Underemphasis.—On the other hand, rightly viewed, the *recognition of syphilis is a positive relief to the puzzled examiner.* This sense of relief has, too, its undesirable side. It becomes a diagnostic straw to clutch at, a lifebuoy which can float the most astounding weight of heterogeneous or puzzling symptoms. In the presence of a positive Wassermann

the th rey or tel fract w h novel t nt yp l l Much of the ph m these rules of thumb t the pres t l t b l e l l l vated n men i e are to the search gregory of mos beh g e m d m g d q reach It is t m ry e t forget e not l real e th t there m y be ph l l psane t t nes d g e h hard edge m ber see ar l heh merge l never en t d l e e alen h f e Il concept of ph l f h special

Clinical and Laboratory Diagnosis. Preventive Outlook In n f ld f medicine i the l abit of prev ntive thought more needed than in l aling w th ph lis The con tant eff rt f the practicing phy ici n the diagnostici n an l the therap t hould be t get one tep nearer the beginning f each manifestat n each accident than did hi predeces or f th year r decade bef re The treatal ility of syphil much greater than that f many of the m re pul licly l scu sed scourge of mankind and it controllal il ty a an infection are ich th t every expend ture of effort in thi lirecti n yield rich return Th treatment of late yphili i the detecti n of early an l latent sy l il an pl en m th t will be repeated empha ized l y the mat rial f ubsequ nt ch pter The Wa sermann te t on the patient with a palpabl li er nd n c mpl nt the pinal fluid te t on the "nervou break l wn th recognit n f th rly tambour secon l sound over the aortic area rath r than the heaving precordium loul le murmurs, and enlarged heart of f ve years later th treatm nt of the yphil tic mother in tead of th child i th essence of n l rn cl nical yphilology

Multiple Attack and Collateral Evidence It at t mes still difficult for the physician sharing the common desire of human nature for tou h tones and "open sesames to realize that yphil will n e wh lly yield to a single diagnostic key The ancient clinical yphil l gy n r xpected it It wa f r the new syphilology to propose first th W sermann and then the luetin tests as diagnostic infallil ilities Critical rev i ion h reduced our hopes toda to the point where *in my estimation it i fair t ay that no ingle procedure* can be expected to identify more than "3 per cent of the syphili which present itself for diagnosi in the average medical clinic T be sure this record is n discredit to the tests which are respon ible f r it Few ingle modes of approach

to any problem in disease can boast so high an average efficiency as the blood Wassermann test, for example. But in raising the efficiency of diagnosis as near to 100 per cent as possible advantage must be taken of all the resources of attack which modern medicine provides and not of one or two alone.

Syphilis is, fortunately, seldom a completely monosymptomatic disease, so that it is usually not too laborious a search to find the positive elements in a complex. It tends, as will later appear in its later phases, where the maximum diagnostic difficulties occur, to be polysymptomatic in its expressions, so that if one line of investigation yields a negative result, another may yield positive. The presenting phase may, however, have a doubtful specificity, as when a patient enters with symptoms of aortitis, negative serologic reaction, no history of syphilis, and generally negative syphilological findings up to the point where one reaches the examination of the spinal fluid. As soon as this is done the familiar combination of cardiovascular and neurosyphilis becomes the presumptive diagnosis following the identification of positive and specific changes in the spinal fluid, even with a negative neurological examination. The identification of much of the syphilis of internal medicine resolves itself into such a search for collateral evidence. The collateral evidence may appear at once in the form of a positive serologic reaction identifying a lobulated liver as syphilitic in origin. On the other hand, a diagnosis may not be reached short of half a dozen procedures, and may even then elude the clinician only to be brought out later by the resolving power of time in the form of repeated observation.

The Problem of Pseudosyphilis.—The decision to leave unaltered in revision the foregoing pages on the clinical approach to syphilis must be qualified by the *changes which are taking place in the viewpoint of the practicing* physician toward the disease. Emphasis on the importance of a high degree of chronic suspicious alertness toward the omnipresence and the difficulties of recognition of syphilis is undoubtedly still well placed, but it is to the credit both of the revived teaching of syphilology and of the conscious effort of the practicing physician to keep abreast of the best his time affords, that the proportion of undiagnosed syphilis is probably materially on the wane. Coincidently with this improvement in diagnostic standards there is developing the usual secondary wave of qualification and reappraisal of diagnostic methods on the one hand, and a wave of overenthusiasm in the use of certain of them, on the other. There can be very little doubt that today, as a result of wholesale application of single diagnostic procedures, there is a good deal of syphilis diagnosed which is not syphilis at all. Error in the performance of some essential test throws the diagnostician off the track and raises suspicions which can be stilled only by the institution of treatment as a therapeutic test, if nothing more. On other occasions the extraordinary facility with which syphilis apes every disease in any field of medicine, leads inevitably to a borderline of confusion in which not only one but a number of really very presentable reasons can be urged for regarding a patient as syphilitic when, as a matter of fact, he does not have the disease. The roentgenogram of a bone, the feel of a liver, a sequence of eruptive events, an incisor tooth, may be the point *on which a diagnosis seems to turn. The large proportion of pseudo-*syphilis probably takes its origin, as Mitchell has pointed out, from partial or weak positive serological tests reported by laboratories not acting under appropriate syphilis clinic control. A proportion of these, steadily diminishing in importance with the perfection of serological tests, represent biological false positives and the nonspecific margin of error of even the best test procedures. Nonspecific therapeutic tests (see p. 151) in which the clinical response of a condition other than syphilis to treatment usually regarded as specific for syphilis itself constitutes the second group of mistakenly diagnosed cases. The third group rests upon the misinterpretation of clinical signs. The

student of syphilis once he has developed the alertly suspicious mind must certainly be on the lookout for the pitfalls of hypersuspiciousness. There is no doubt that the place of syphilis in general medicine can be exaggerated by the enthusiast who does not maintain a system of balanced check upon his interests and his ferreting instinct. On the other hand, the pleasure of bringing to book by the detection of some egregious "flunk" the ultraconservative mind which defines "syphilologist" as one who calls everything syphilis is the keenest in the whole realm of intellectual pursuit. The expert surrounded by an elaborate machinery and constantly confronted with the extraordinary versatility and imitative capacity of syphilis encounters his pitfalls in a tendency to excessively fine-spun decision. Fear on the part of the average physician of overlooking the possibility of syphilis leads to such tragically familiar mistakes as treating epithelioma of the tongue as syphilitic to the point of fatal metastasis, or the performance on a young man with a herpes progenitalis of multiple Wassermann tests and darkfield examinations, two spinal punctures, a circumcision and a biopsy which removed a very fair portion of his glans penis. Of the very puzzling and often serious problems which confront the consultant as a result of serological inaccuracies the following example introduced here to whet the interest of the reader in the more critical considerations of Chapter III (biological tests) is offered.

A man of fifty-three whom Stokes personally examined in March, 1917, exhibited the clinical symptomatology of a very early paresis with typical and unmistakable serological changes in the blood and spinal fluid, including a positive Kolmer and Kahn test on the former and a positive Kolmer-Wassermann with a classical colloidal curve on the latter. Owing to some technical difficulties encountered by the home physician in treating his case on recommendation, he had only a very moderate amount of treatment while away, which could not possibly have changed his serological reaction materially. To the great surprise of Stokes, a letter was received from the physician who dealt with a technical complication, which read as follows: "He was suffering from an injection abscess of the buttock. We opened it and drained about 2 pints of sterile pus. He has made a good recovery. His blood and spinal fluid are negative. If you have any suggestion relative to future treatment I would welcome them very heartily." Experience with the biology of the disease, that stabilizing and determining factor which often saves the day for the consultant, led J. H. S. to doubt the accuracy of this report on blood and fluid though he had every personal confidence in the man who quoted it. On his insistence the patient revisited him at once and a second spinal fluid examination was performed by J. H. S., the fluid from which was examined by two laboratories, yielded results practically absolutely identical, both on blood and spinal fluid Wassermann, cell count, globulin estimation and colloidal test, with those positive results which he had obtained in the first examination. J. H. S.'s situation as consultant now became one certainly not likely to endear him to the home folks, for "who is less beloved than he who revealeth an error?" If, accepting the report of the home physician's hospital on this serology, J. H. S. had proceeded to advise further in regard to his treatment without re-examination, the patient would have gone from bad to worse. Contrary to general belief such gross and obvious mistakes are much too frequent. Only a most devious explanation involving hypothetical possibilities such as the transient effect of a Netter abscess, saved the face of the situation in the eyes of those concerned. This patient's life literally hung on the inaccuracy of this report. The abnormal spinal fluid findings have been confirmed by a third examination and two years of consistent energetic treatment has finally yielded a good therapeutic result.

In another instance five different Wassermann tests, supposedly divided between two laboratories, were all sent to the same laboratory inadvertently and all were returned strongly positive. The institution of treatment so changed the diagnostic perspective in the case that it probably never will be possible to determine whether or not this patient has syphilis, but every evidence points against it. His chief complaint of diarrhea, which was, upon the finding of the false positive Wassermann, interpreted as syphilitic in origin, is one of the rarest complications of the disease. The clinician's examination of the case came to an end when the positive Wassermann was discovered and it was only subsequent investigation over the head of the positive blood test which proved that the diarrhea was amebic in origin. This man was by no means the victim

of diagnostic incompetence and his serological tests were performed in a private laboratory under excellent medical direction. The more complex possibilities of pseudosyphilis, based on combinations of clinical and serological signs, are illustrated by the following case. A virgin of thirty-six, in previous good health complained of what was thought to be urethral caruncle. Immediately following the next menstruation an acute urethritis developed, the smears showing a short diplobacillus in two competent laboratories. Following the use of an enema the rectum apparently became infected with the same organism, giving rise to bleeding and pain. The vagina became involved, with severe pain and spasm, and the second menstrual period produced only a small amount of bloody discharge with a fetid odor. In the ensuing three months the vaginal condition improved under local treatment and then suddenly an eruption appeared, accompanied by vulvar itching. Six months later after an interval of comparative comfort, a gingivitis appeared followed by symptoms of stiffness and swelling of the neck glands and pain in both shoulders. A glossitis followed and a painful spot appeared in the left chest. Coincidently a general eruption developed which was of a florid red, itched somewhat and was accompanied by mouth lesions from which a distinct pellicle or skin could be picked. Patches were most numerous on the gums. A sore spot appeared on the head in the left frontal region with a visible swelling accompanied by a fever to 101 F. A skull roentgenogram, taken three months later showed the typical charnation of the inner table frequently observed in lues. The serological history in this case followed an up-and-down course with curious inconsistencies and reversals not in keeping with biological expectancy in the ordinary course of the disease. Even a spinal fluid examination, which was negative to the Wassermann and colloidal tests, showed a slightly increased cell count, a finding which had been noted by Herrick in nonspecific systemic infection. Diplo-organisms were again found in a vaginal smear and the patient's fever continuing, treatment with an arsphenamine was begun with very slow and atypical response. The upshot of the entire case was a complete recovery and the syphilological evaluation compels the conclusion that she had never had the disease. None the less, at one point after another during the course of her nonspecific infection, individual isolated signs or serological returns could easily have been interpreted and in fact were interpreted by competent observers as evidence that she had a syphilitic infection. This case now of more than four years standing has never at any time given further evidence of what might be interpreted as a latent or inactive syphilitic infection.

The Intuitive and the Problems of the Consultant.—All the cases above described, and particularly the last one, furnish excellent illustrations of both the logical and the intuitive phases in the diagnosis of syphilis. Desirable as it is that medical acumen and procedure be free from partial and ultrasubjective interpretations, it can never be wholly freed from them. Intuitive diagnosis has a legitimate place in the identification of syphilis when it is the product of long experience with both the broad aspects and the special relations of the disease. In one particular field, that of the recognition of heredosyphilis, for example, intuition holds a peculiar almost unique place among diagnostic criteria. Much as one might wish to eliminate it, the intuitive is a factor in every diagnostic decision which involves the weighing of evidence. It gives to the pronouncements of even the most objective of syphilologists the same temperamental and personal quality which enters into all medical judgments. Realizing this, no individual clinician is living up to his obligations with respect to syphilis who is not questioning himself searchingly from time to time as to this factor in his work, and as to the consistency and logical development of his thoughts concerning the disease. Just as the farmer through lifelong contact with growing crops, and the bacteriologist, as in the case of Noguchi, or the parasitologist in the case of Schaudinn, reaches conclusions which arouse, sometimes, the skepticism, sometimes the surprised admiration of the bystander so the decisions of the consultant in the syphilological field, in part subconscious and based upon an intuitive and experiential knowledge of the biology of the disease, may at times fail of rational analysis even though time and the course of events prove them to be correct. The best antidote for a disposition to be overintuitive in such a capacity is the determined writing out, in notes and correspondence of the full detail of logical analysis applicable to the individual case.

THE EXAMINATION OF THE PATIENT

The ideal approach to a syphilological examination is purely objective. In other words, a complete study of the findings precedes the taking of the history irrespective of the chief complaint. The practicability of this method of approach under office conditions may however sometimes be questioned. The taking of a history if it is painstakingly done and follows all the essential

leads in the nece sary detail provides an acquaintance with the patient that greatly a sists in the final appraisal of the case After a con iderable experience with various printed form technics of taking the hi tory of the syphil s patient, we have finally aband ned tl m in favor of a mimeographed outline or desk card containing the lead which hould be foll wed The history i then tak n

with the card bef re the inquirer the lead are noted as they are taken up on the blank heet and the data written in by hand Such a work sheet or standard history guide a used in our offices and clinic at the University of Pennsylvania is gi en in Fig 12

In general it may be said that the trend of the history-taking for early syphili should be toward specially searching inquiry into the circumstances

time relations and persons involved in exposure the onset and presence of lesions of the mucous membranes skin anus and genitalia the family responsibilities and contacts involved the possibilities for the future such as engagements to marry informal sexual partnerships and so forth the darkfield serological and other examinations on which a previous attempt at diagnosis may have been based the time relation of these procedures to each other to the exposure of other individuals and to the institution of treatment and the actual facts in detail as to drugs dosage time intervals between treatments, number of treatments per course and especially rest periods without treatment or lapses from treatment on the patient s own initiative These time relations are of vital importance in estimating the status of any given case from the standpoint of modern therapy It is for this reason that the previous advice and management of any given case is summarized on a chronological basis in Fig 12.

The inquiry and examination in patients with latent syphilis (no cutaneous lesions and a duration of a year or more since infection) should concentrate on the time relations and general adequacy of previous treatment, on marital and other sex contacts, the status of the family and evidences of recurrence, clinical or serological The matter of a complete spinal fluid examination must always be carefully inquired into.

The emphasis in patients after the fifth year or even before should be upon the symptomatology arising from important viscera and systems in process of impairment or actually injured by the disease. Gastrointestinal symptoms and jaundice deserve special inquiry the former because they are the expression quite often of injury to the nervous system rather than to the gastrointestinal mechanism itself The cardiovascular and nervous systems, the two great fields of critical damage and often obscure symptomatology must be painstakingly gone over if the weaknesses of our present poor showing in the matter of prevention are to be remedied These lines of inquiry are outlined in Fig. 12 (Item 4 under Present Trouble)

The Physical Examination for Syphilis.—It is impossible for one thrown into intimate contact with syphilological diagnosis to do otherwise than reluctantly concede the truth of the dictum sponsored among others, by Billings, that one of the principal defects of medical practice at the present time is failure to examine the patient adequately The baseline physical examination of the patient at the outset of his infection is the starting point for all subsequent estimates of clinical progress, favorable or unfavorable Yet how often on feeling a palpable liver for the first time or noting a definite hypertension with accentuated aortic second sound does the consultant find himself without a point of reference in the form of a previous properly performed physical examination on which to base his decision as to whether symptoms and signs which he detects are new and due to the advance of the disease or old and related to secondary or adventitious causes

Figure 13 presents a standard guide sheet which is the result of fifteen years of effort to reduce the leads and the essentials in the examination of a patient for syphilis to minimum essentials and the proportions of a card for desk reference. It will be noted that the arrangement of the examination is by systems rather than by regions. While this might seem at first to lead to reduplication of effort and movements on the part of both patient and examiner the difficulty we have experienced with it on this score is negligible in comparison with the very great advantage derived for the consultant from

the sorting out of findings under a satisfactory scheme of classification for appraisal. The use of such a schedule of examination need not in any way interfere with the extension of any particular lead in whatever direction the findings in the case may seem to indicate Thus, for example, it is not proposed

Mentality An excellent test (Foster Kennedy) is to have the patient write an unprompted letter of two or more pages.

to regard the survey of the central nervous system here given as an adequate neurological examination for all differential diagnostic purposes The examination as given however reveals clearly the types of abnormalities characteristic of neurosyphilis in the large majority of cases and brings to light in a

search thus directed enough suggestive clues to protect against the majority of diagnostic pitfalls provided each special clue is followed up when indicated

The time required under office conditions for an examination of this degree of thoroughness ranges from thirty minutes to two hours and is materially shortened as the examiner's experience grows. The instruments required aside from those for distinctively laboratory manipulation such as darkfield and blood specimens for serological test, include stethoscope steel tape soft rubber reflex hammer tongue depressors, flash light, tuning fork (C-128) and a pin stuck transversely through the end of a wooden applicator for testing pain-touch differentiation

Fig. 14.—Routine examination of anogenital region in women. A speculum examination in the lithotomy position is desirable if there is marital introitus and suspicion of early syphilis. A responsible adult woman should be present at the examination of girls under eighteen years of age Rubber gloves should be worn.

Emphasis should be placed on the conditions under which a physical examination for evidence of syphilis is conducted. Good light is essential particularly for inspection of the skin orifices and flexures of the body The ideal light is north daylight but a tungsten daylight bulb can be substituted by a practiced examiner The light should be on a movable stand which should be so placed that the regions mentioned can be absolutely flooded with illumination Not only does the disease escape unrecognized when examinations are conducted under poor or improper lighting conditions, but the examiners are themselves subjected to dangers which they little realize The macular secondary syphilid is difficult enough to see under the most favorable conditions By artificial light it is invisible five times out of ten. Shadows cast on impor

tant points result in serious errors in diagnosis, and in contact unawares, with lesions that swarm with the *Spirochaeta pallida*

We have known a trained observer to pass the bare fingers over a condyloma on the fourchette which even his preliminary inspection had not disclosed because the patient was examined by a powerful overhead light a little too far back with reference to the position of the patient so that a tiny lunette of shadow hid the lesion.

Fig 15

THE CARDINAL SUSPICION AROUSERS OF SYPHILIS

Symptom	Sign
1 Miscarriages and stillbirths.	1 An indolent lesion with one-sided local lymph node enlargement anywhere
2. Protracted headache	2. The genital or anal erosion, ulcer papule ring, button or scar
3 Pseudotuberculous and pseudorheumatic symptoms in the twenties.	3. Patchy hair loss.
4 Hoarseness and aphonia (protracted)	4. Any widely scattered nonvesicular eruption lasting more than two weeks.
5 Pain (especially nocturnal) persistent in isolated bones and joints.	5 General lymph node enlargement.
6. Failure to heal, especially skin and bone.	6. Palpable induration and arciform configuration with scar in any skin or mucosal lesion.
7 Persistent vomiting	7 The atrophic smooth or deeply scarred, or heavily leukoplakic tongue
8 Nocturnal dyspnea.	8. The locally enlarged, thickened, or tender bone especially tibia or shoulder girdle
9. Periodic vomiting.	9 "White" or phlegmonous swelling of any joint or pair of joints.
10 Failing vision.	10. Skin adherent and scarred over bone
11. Double vision.	11 Palpable liver or spleen.
12. Sticking, sharp or "lightning" (cord) pains.	12. The "tambour" aortic second sound
13. Bladder hesitancy leakage	13. The pupils, unequal, slow or fixed to light.
14 Neurasthenia and conduct slump in adults, especially after 40 years of age	14 The dropped eyelid.
15. Pink eye lasting more than 10 days.	15. Absent A. and K. reflexes.
16. Sudden deafness.	16. The positive Romberg.
17 Conduct slump in a child.	17 The sudden cord paralysis.
	18. The caved or sunken nose
	19 The teeth—Hutchinson upper central incisors, Moon 6-year molars.
	20 The facies of congenital syphilis.

Those who desire line-drawings of the technic of regional examination will find them in the first and second editions.

Certain significant points in examining the skeletal system include emphasis on the tibia as a frequent seat of osseous change The fusiform thickening of the middle third of the bone should be felt for by passing the bone between the thumb and first two fingers (Morton Smith's maneuver) and feeling for the rounding of the anterior face, as well as anterior bowing of the edge with the flats of the fingers or hands. In every inspection of the patient it is wise to

Skin, general (including scalp)	Mottled or spotted skin nd neck. Papules t ngle of mouth Erosions on lips. Ringed lesions. The fleshy or indurated feel of lesions. Faint rashes on tru k. Faint eruptions, rists and forearms. Goose flesh appearance (follicular lesions) and grouping in lesions.	Chronic small ulcers or groups of ulcers, nodules or scars. Ringed, arciform nd kidney-shaped lesions and similar scars, thin nd paper like or in hich skin is fixed t bone. Scarring of the face ithout distortion or ectropion.
Mucosae.	Erosions inner surfaces of lips nd under tongue or far back at sides. Papules on the dorsum fa back. The extragenital chancre or scar (seen but not suspected) Bismuth line	Hatching of lips. Scars nd rhagades ngles of mouth Nasal septum per forations. Early anterior palatal perforation. Leukoplakia at commissures. Tremors nd indurations in the tongue. Scarring of tongue nd fauces.
Teeth and tonsils.	Dental condition ith reference to treatment Pyor rhea, devitalized teeth, tonsillar lesions, especially erosions.	Focal infection possibilities.
Palms and soles.	Flat papules, pink t dark red, ith collarettes of scale. Often palpable. May be merely pink spots.	Circinat or gyrat groups of papules or lines of infiltration bordering reddened reas of thinning Paronychial and nail changes. Fusiform ellings.
Anus and genitalia.	Size and condition of vaginal introitus. Chancre and chancre scar (avoid phy mosis) Vaginal discharge Induration of intra-urethral chancre (palpate in long axis). Condyloma or mucous erosion disguised "hemor rhoid Condyloma or moist papule hidden in fold, especially gluteal Cervical chancre or erosions in women. Localized lymphangitis of penis ("pipestem") Mucous erosions and ringed lesions, posterior surface of s rotum.	Chancre scar Nodules in testis or epididymis. Odor of urine (incontinence) Hy drocele in children Fistula-n-ano. Stricture (rectal)

Fig 16.—Continued

Body Region	Early Syphilis	Late Syphilis
Lymphatic system.	Unilateral satellite adenopathy of extragenital chancre Submammary nodes. Visible cervical and post auricular adenopathy Palpable inguinal and epitrochlear nodes usually recognized Palpable spleen.	Gummatous lymphangitis (leg) Gumma of the lymph nodes (usually mistaken for tuberculosis) Palpable spleen often overlooked.
Skeletal system.	Painful spots over bones, especially skull and tibia Periosteal lesions, doughy deep, or superficial (make deep pressure or pinch firmly)	Floating patella (fluid in knee). Lateral play or hypermobility of joint (early Charcot) Stiff back (have patient stoop) Comparison of symmetrical joints. Juxta-articular nodules. Flattening of nasal bridge Minor destructive scarring ala nasi. Localized nontender exostoses, fusiform thickenings and irregularities of long bones, especially tibia. Thickening of inner third of clavicle and sternoclavicular joint. Costochondral and sternal thickening, edema, tenderness. Bumps on the skull. Condition of fontanelles.
Liver and spleen.	Slight jaundice Palpable enlargement (one or both often overlooked)	Palpable enlargement. Nodules and tumors. Abdominal fluid. Jaundice Compensatory venous enlargement.
Cardiovascular	Congenital and nonsyphilitic valvular lesions.	Supraclavicular and cervical pulsation. The early accentuation of A2 with slight rise in blood pressure and slight enlargement of heart Widened aortic dulness The aortic systolic and diastolic murmurs (heard but minimized or ignored) Markedly unequal blood pressure in the two arms Slight signs of decompensation (breathlessness, reduced exercise capacity slight edema of ankles) Early upper abdominal aneurysms (popliteal, etc) Venous ectasis (see prenatal syphilis)

compare the size of individual bones with the frame as a whole and to recognize the heavy clavicle of the prenatal infection as a suspicion-arouser Double swollen knees should not be put in casts without Wassermann testing and swollen joints, particularly knees should never be aspirated, until the pupils are examined.

Fig. 16.—*Continued.*

Body Region.	*Early Syphilis.*	*Late Syphilis.*
Nervous system.	Transient pupillary inequalities. Early seventh nerve rolings. Nystagmus, tinnitus, unilateral deafness (N viii)	Pupillary inequality due to unilateral lighting or congenital (not pathologic). Adie spastic pupillary syndrome Posterior synechia with fixation. Slight extraocular muscle weakness or paralysis. Nystagmus. Slight ptosis. Corneal opacities. Slight residua of hemiplegia (motor function) N viii. Abdominal and cremaster reflexes. Hand writing and composition tests (have the patient write a one-page letter). Sensory changes on the face Muscle atrophy and twitching

In the examination of the nervous system it should not be concluded that fixed pupils are necessarily Argyll Robertson. In a survey of syphilis in rail road men, 65 per cent of those who had the disease had pupillary signs of it entirely unrecognized though their eyes had been repeatedly examined by specially trained examiners for years The trouble was, that emphasis was all on color vision and visual acuity We have even had as a patient a railroad eye examiner who had grossly unequal Argyll Robertson pupils and did not know it.

In testing reflexes it is important to estimate the general tone of the reflex mechanism and never to call a reflex totally absent unless it does not respond to reinforcement. A hypotonia can be judged only in the light of all the reflexes and a uniform diminution. Again some patients in a state of high nervous tension, manage consciously or unconsciously to "hold" the reflex so that it may appear to be absent or diminished A hand on the contracting muscle and repeated reassurance may bring out the reflex after a few minutes effort. The Achilles reflex, in our experience, can be reliably and convincingly obtained only in the kneeling patient and the attitude should be comfortable for it can be completely veiled by a strained attitude. The cremasteric and umbilical reflexes should never be omitted and one writer on syphilis has even maintained that absence of these two reflexes in a person with a history of old syphilis justifies lumbar puncture In doing pin tests for pain sensation, the patient should be watched to see that he is not responding to differing degrees of pressure rather than to actual pain sensations in calling out "sharp" or "dull." Patients should, moreover be asked if they have been practicing such a test as the Romberg for many of them do The normals of the bone fork in testing vibration sense must be learned by experience. In testing for anesthesia, the circumanal region should be remembered If cutaneous lesions are present the center should be compared with the periphery before making a a diagnosis of neurosyphilis. We have seen a patient presented before a national society in whom failure to do this test and to feel the ulnar nerve, humiliated the presenter by his failure to recognize leprosy with a positive Wassermann reaction by simple neurological signs

CHAPTER III

THE FUNDAMENTAL DIAGNOSTIC TESTS IDENTIFICATION OF SPIROCHAETA PALLIDA

The Darkfield Examination

The necessity for the use of the darkfield in the early diagnosis of syphilis arises, as has been previously intimated in the characteristics of the organism itself The exceptional difficulty in staining it and the fact that its living characteristics rather than its dead form constitute the essence of its differential identification make observation of it in the living state a practical necessity for diagnosis For more than a decade therefore, with little regard for the practical considerations in the case syphilologists and public health officers have been urging on the medical student and the practicing physician the systematic use of the darkfield in the office for the identification of the casually-entering patient with early active syphilis. Only the experience of teaching darkfield technic to medical students has convinced us that the use of the darkfield as an instrument for the early diagnosis of syphilis has theoretical rather than practical value in the movement against the disease as a public health problem so long as the utilization of the procedure is left to the initiative and resources of the practicing physician. The necessity for special equipment in the form of sub- or supra-stage darkfield condenser or cardioid condenser which is of relatively little use in other fields of work the necessity for technical training, which can hardly be less than two weeks and which is readily forgotten or never given in the crowded regimen of the medical schools, make the examination of secretions by the darkfield an affair for laboratories, clinic centers and specialists. Darkfield examination can be developed by public health authorities into a centralized procedure like the identification and culture of the diphtheria bacillus That even laboratories and individuals claiming to make diagnosis of syphilis by the darkfield examination require supervision, is evident from complaints with reference to the work of commercial laboratories and the experiences of syphilis clinics which receive diagnoses made in this way by outside sources For this reason, a consideration of the darkfield examination in the diagnosis of syphilis is here given in detail for the benefit of the specialist, would-be specialist or physician with a special interest, while the course which the general practitioner is advised to pursue in securing early diagnosis of early lesions is separately outlined

Let it not be imagined that these remarks relative to the limited availability of the darkfield for the practitioner in any way affect the supreme importance of this form of identification of the organism for the diagnosis of syphilis at the present day Little short of a miracle will be either the serological test or the staining technic which can replace the darkfield procedure in identification of the *Spirochaeta pallida*. Previous optimism, based on hopes inspired by the skill and versatility of serological friends, has been rudely shaken in this particular by the expressed opinion, after years of effort, that it is improbable that any form of test of the secretion or serum from the infectious early sore can be made simple enough for ordinary office and perhaps even completely satisfactory laboratory use.

In 1905, when Schaudinn identified the *Spirochaeta pallida*, no satisfactory darkfield equipment existed. E. Hoffmann had used the Zeiss dark chamber in a search for the organism of

syphilis in 1904, without success, and nothing of the sort we know today was available until Reichert of Vienna demonstrated the organism with the Reichert substage condenser in 1906 (Ivory). The darkfield itself is, of course, a modification of the so-called ultramicroscope devised by Siedentopf and Zsigmondy for the study of the physical constitution of colloidal solutions. The principle employed is a surprisingly simple one: essentially that of the mot or dust particle visible in a sunbeam. Thus, in side or lateral illumination against a dark background, refractile particles stand out brightly defined in the transverse illumination. In the darkfield microscope the light from a powerful source of illumination is reflected upward by the substage mirror as in the ordinary microscope, and then thrown horizontally across the field at the level of the slide containing the object, so that the observer, looking down upon it, sees the specimen illuminated by horizontal rays comparable to those of the sunbeam in the darkened room. Direct rays are cut off by an opaque disk in the center of the condenser. The object in the microscopical field then stands out in contrast to the dark occluding disk background below it with remarkable brilliancy.

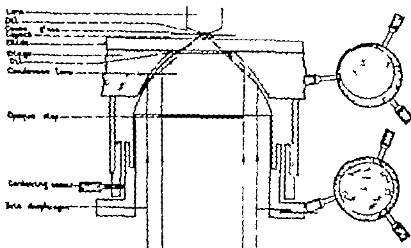

Fig. 17.—Schematic section of the microscope through stage, central aperture and oil immersion lens, showing the substage darkfield condenser in place and a specimen ready for examination, with immersion oil above and below the slide. To the right are two small schematic drawings of the condenser face by darkfield illumination, as seen through the low power of the microscope before the slide containing the specimen is in place. In the upper sketch the condenser is not properly centered, and the etched circle is eccentric to the margin of the field. In the lower sketch the condenser has been properly centered by the knurled set-screws, and the etched circle appears concentric with the margin of the field. Careful centering is important to proper illumination and definition.

Darkfield Equipment.—The improvisation of darkfield equipment under ordinary office conditions was described by Coffin in 1920 and further endorsed by Light in 1930.

According to Coffin, a piece of black paper the size and shape of a quarter pasted on the center of the lower convex surface of the Abbé condenser of the ordinary microscope, will make a darkfield apparatus for examination of the *Spirochaeta pallida*. The high, dry (4 mm.) objective is used and the light regulated with the lower shutter of the condenser. Light points out the desirability of the funnel stop and oil immersion lens mentioned later. A 75- to 100-watt lamp enclosed to prevent glare can be used to supply light to the reflecting mirror of the microscope. Good darkfield work can be done in the writer's experience with the ordinary Welsbach gas mantle, properly screened, and it is even possible to see spirochetes with the aid of a good Argand or student-lamp kerosene burner. We personally still cling to the small arc lamp in spite of its sputter and constant need of adjustment as the most intense and satisfying source of illumination we have used.

Darkfield Condensers.—Three types of darkfield condenser are in use at the present time The first is the flat-table type placed on top of the microscope stage with the darkfield condenser in the opening usually occupied by the Abbé substage condenser The second is the paraboloid substage condenser shown in Fig 17 The third and most recent development is the cardioid or hemispherical condenser Whatever type of condenser is employed, the devices for centering it must be thoroughly understood; it should be possible t focus the condenser to some extent to accommodat t the thickness of an overthin slide by up-and-down adjustment nd there should be a diaphragm below the condenser for regulating the amount of light admitted.

The one-tw lfth oil immersion lens is much superior to the dry lens for darkfield work but requires funnel stop to be inserted int the casing of the objective above the len system to cut dow the normal perture If this stop is not used the field is obscured by a glare through which nothing can be seen.

It is not intended to make the use of the darkfield ppear unduly discouraging to anyone who desires t take the necessary time t master it. From the interstices between the gums and the teeth any amateur can obtain multitudes of spirochetes for examination and can practice himself thoroughly on the details of the microscopical technic. Familiarity with the *Spirochaeta pallida* can be obtained only by seeing the organism itself and differentiating it from the types which it resembles. So far as the commoner contaminants of genital lesions are concerned, the knowledge is readily acquired. It is in dealing ith lesions on the mucous membranes that the possibilities of error become so great that none but the really experienced should undertake final nd differential diagnosis.

Setting Up th Equipment.—It is desirable in general in clinic and laboratory practice to maintain an instrument constantly set up for darkfield work, if the most satisfactory conditions are t be obtained. Information on satisf ctory microscopic units completely and permanently set up and requiring little or no adjustment can be obtained from optical manufacturers. On the other hand, it is entirely possible to take dow and set up equipment with each examination The centering of the darkfield condenser is an important part of the technic. On the face of each darkfield condenser bove the black disk, is ground circle (Fig. 17) slightly smaller than that represented by the low-power field of the microscope. When the condenser is inserted in it p oper place this circle is to be exactly concentric with the edge of the low-power field. The ad justment is made by looking through the low-power ocular and objective t the face of the condenser hich should be illuminated by the light reflected from the mirror below precisely as for darkfield ork. The condenser is then moved about by hand or by set-screws in the substage or by levers in the cardioid condenser until the bright circle is exactly concentric with the black margin of the field. The illumination is then adjusted by shifting the mirror below the stage and by moving the source of illumination nearer and farther (unless it has been set up at an optimum distance) until the circle is equally bright in all parts of its circumference. The condenser may then be moved up and down until the field has reached its smallest and brightest and the instrument is then focused and ready for use

Slides and Coverglasses.—For the most satisfactory operation, both the slides and the coverglasses used in darkfield ork should be sorted from stock by measuring with micrometer caliper only those of thickness specified by the manufacturer of the darkfield equipment being used in the ork. If the slide is too thick, the light comes to focus below the object on the surface of the slide and no satisfactory correction is possible. If the slide is too thin, Harrison points out that it is possible, by focusing the condenser t bring the light t focus upon the object thus obtaining satisfactory illumination. In the use of the oil immersion lens drop of im mersion oil is placed on the face of the darkfield condenser the slide containing the specimen is then laid on it ith an even contact of the oil between the two surfaces and entirely free from bubbles. A drop of immersion oil is then placed on the surface of the coverslip and the oil im mersion lens employed as usual. It is essential that slides and coverglasses shall be absolutel clean, free from scratches and defects. Casselman quotes Stitt as recommending paste of Bon Ami and water smeared over the slides and coverglasses, hich are then stored with the powder dry over them. Before use they should be polished, washed and dried.

Additional items which should be at hand before darkfield examination is begun include crystal-clear immersion oil, one pair of absolutely perfect rubber gloves, one small scalpel for scraping lesions, several long, thin capillary tubes with cotton plugs at the larger end for col lecting specimens from surfaces hard to reach several gauze sponges and supply of sterile phys ologic salt solution.

It should be emphasized that the handling of darkfield material and of instruments and equipment in use in the work is potentially dangerous. A

thorough alertness and awareness of every movement and the use of perfect rubber gloves in cleaning up equipment as well as in obtaining the specimens is an essential precaution against accident. All accidents moreover must be regarded as serious and the question of prophylaxis instantly considered (see p. 1227).

IMMEDIATE DARKFIELD EXAMINATION

Obtaining the Specimen.—It is extremely important to select for darkfield study lesions which are as young as possible, as nearly untreated as possible and as clean and free from detritus and secondary infection as possible. This triumvirate of requirements is seldom enough met in actual practice and, in fact, should be made the text of a systematic educational campaign among physicians and laity. Old lesions contain relatively fewer organisms because of the destructive effect of the local tissue reaction; treated lesions often have their surface organisms completely destroyed by escharotic and cauterant applications, and dirty lesions usually contain the *Spirochaeta refringens* which to the inexperienced is confusible with *Spirochaeta pallida*. It is for the purpose of removing mechanically the necrotic tissue favorable to the growth of the former that thorough cleaning of the lesion with scalpel, dry gauze and salt solution (Hoffmann also advises in some cases the use of alcohol to promote the flow of serum) is essential. Surface spirochetes obtained from pellicle, crust or detritus are always untrustworthy. The organism of syphilis is found in the serum from the deeper layers of the lesion.

Mouth and Throat Lesions.—The examination of lesions about the mouth and throat must be surrounded with special precautions and an expert should pass on all such specimens on account of the ease of confusion of the *Spirochaeta pallida* with mouth organisms. Whenever possible specimens from these regions should be obtained by aspiration of the bases of the lesions or by dissection of a small piece (Hoffmann) in the case of the tonsil, after thorough cleansing. Large cotton pledgets may be used to keep saliva and contaminating solutions away (Harrison).

Mahoney and Bryant (1934) found 40 per cent of nonsyphilitic tonsils to contain a form of spirochete, probably *T. macrodentium*, almost indistinguishable from *T. pallidum*—an indication of the unreliability of darkfield diagnosis in tonsillar lesions.

Gumma.—Darkfield examination of late gummatous lesions for syphilis is a futile procedure in the overwhelming majority of cases, for the *Spirochaeta pallida* is seldom present in sufficient numbers to be demonstrable by this method.

Satisfactory Specimen.—While a few blood cells are desirable in the darkfield serum, a marked visible contamination with blood renders the specimen almost useless. On surface lesions, if blood appears it may be blotted off and within a few moments enough clear serum will exude. This is collected by touching the surface of the coverglass to the lesion, a droplet 2 or 3 mm. in diameter being of sufficient size. It is essential that the film be thin, but not so thin as to dry rapidly. Once a good clean specimen of serum is obtained with perhaps 5 to 15 red blood cells to the oil immersion field, systematic alert and intensive searching should be begun and continued for fifteen minutes as an absolute minimum. A better plan is to search repeatedly but for shorter intervals over several days, two specimens being taken each day provided the lesion is large enough not to be ablated by this procedure.

Fig 18.

SUMMARY OF DARKFIELD TECHNIC

1. *Have at hand* rubber glo es (no pinholes) forceps; dry gauze; scalpel, not too sharp for scraping; immersion oil; slides nd 00 cover-glasses in alcohol. Great care must be taken t remov all the reagent from slides nd covers.
2. Clean t 00 cover-glasses nd t slides ith ter and 75 per ent. lcohol
3. Put on rubber gloves
4. Be sure the darkfield lamp is working and the darkfield i centered.
5. Have the patient lie down if possible He may f int.
6. Select the cleanest nd firmest based lesion vailable.
7. Pinch fairly firmly bet een the left thumb and index-finger and rub off exudat ith dry gauze until base is clean and bleeds slightly hen pressure is released. If the lesion is dry remov crust ith scalpel and scrape lightly
8. Release nd make pressure on lesion several times wipe off blood, nd lightly touch the cover-glass to the clear serum. The drop on the glass should be bout 3 mm in diameter Place t once on slide nd press int close cont ct with clea instrument.
9. Dry lesions, phymotic lesions, old lesions (over tw eeks) sometimes yield rich fields by putting constricting rubber band around penis for from ten to fifteen minutes until there is definite edema
10. Place drop of immersion oil on darkfield condenser face and place microscope slide on stage, cover-glass up. *The oil below the slide must make even contact ithout bubbles.*
11. Place another drop of immersion oil on cover-glass and examine specimen with oil immersion objective in the usual way
12. Make second, nd even four or fi preparations.
13. Search the best specimens for from seven to ten minutes each.
14. Clea up the instrument soon you are through using it.

Fig 19

CAUSES OF TROUBLE IN DARKFIELD WORK

1. Poor equipment, or equipment not adapted t the instrument with which it is used.
2. Dirty cover slips, scratched slides, air bubbles which fill the field with glare. Bubbles in the immersion oil may cause trouble
3. Poor lighting. Not less tha 75 to 100 tt tungsten bulb is desirable
4. Poor centering of condenser Impossible to get even illumination. Follow maker directions exactly
5. Taking down and setting p equipment. If much ork is done separat microscope should be kept set up for this purpose.
6. Forgetting to put funnel stop in oil objective. A diffuse glare result
7. Not getting th light from the enter or brightest point of the lamp, makes the field uneven, or dim, or gives refraction rings (halos) around the objects. T correct, shift mirror about until the best illumination is secured This must usually be done for each specimen or t each sitting
8. Too much oil on condenser face. Floods the condenser nd ma spoil equipment by getting oil under nd loosening opaque stop or disk.
9. A glare of light bove the stage from indow room illumination, et A darkfield orks t best dvantage in dark room or box
10. Too thick or thin cover-glasses or slides. Hard t illuminate. Adjustable
11. Too much serum. Makes field seem afloat, hard to focus, very "jiggly
12. Too much blood. C see little except rouleaux of blood-corpuscles
13. *Currents in the field.* Due to dirty cover-glasses or slides pressure of objective on cover-glass too much serum, hich ppears t cover-glass edge drying, due to heat, draft, etc oil hich ha run over the edge of the cover-glass (too much oil or orking too near edge of cover)
14. A dirty specimen. Swarms ith miniature suns (pus cells), fibrin, and dventitious cocci and other organisms

A maxim of J H.S s preceptor Professor Wile gives the gist of the matter "Look till you find them." The more determined the worker the higher his ultimate score Once an experienced user of the darkfield has the intuitive

sense that he ought to find the organism in the lesions he is examining, he will spend an hour on several good specimens The irksomeness of the repetition is lost in the glory of the find One of our assistants succeeded in establishing the identity of a treated lesion in the face of every odd by finding the *Spirochaeta pallida* on the twenty-first darkfield search on the sixth day after the lesion was first seen and while the Wassermann test by one of the older technics was still negative

It is seldom given a fresh untreated lesion that two or three typical *Spirochaeta pallida* are not found in the first field and from this average their number may vary from 12 to 15 in each oil immersion field to one or two in an entire specimen When the organisms are so few the trustworthiness of the find must be critically considered and expert opinion on the morphology of the organism should be secured

Obtaining Specimens from "Dry" and Previously Negative Lesions.—If the initial search is a failure hope should by no means be given up "Dry" lesions from which it is difficult to obtain serum may be subjected to suction Chambers devised a suction device consisting of a syringe connected with catheter tubing to the barrel of a second syringe Phimotic lesions and old lesions (over two weeks) sometimes yield rich fields by putting constricting rubber bands around the penis for ten to fifteen minutes until there is a definite edema. Igersky (1034) obtains deep serum by cauterizing lesion base or edge with the platinum loop In serial examinations, saline soakings or gentle cleansing of the lesion will often bring the organism to the surface E. Hoffmann also employed the excision of a small piece of tissue or the making of a transverse vertical incision through the upper layers of the lesion. Chambers has applied the Krajian modification of the Dieterle method of section staining to the examination of small slices from the edge of the chancre (see stains)

The technic of aspiration of the base of old or even actually healed lesions practically identical with that used for the aspiration of lymph nodes (see below) often yields satisfactory specimens A small needle passed horizontally into the base of the lesion (not vertically) is employed with an aspirating syringe

Inaccessible and Unusual Lesions.—The *Spirochaeta pallida* may be obtained from cutaneous lesions on the dry surface of the body occasionally by careful aspiration of the individual macular lesions of a roseola and by scraping the bases of syphilitic pemphigus bullae on the palms and soles of syphilitic infants Hoffmann aspirates the palpable border of lesions on the foreskin which are causing phimosis in order to do away with the necessity of retracting the foreskin The aspiration is made directly through the skin of the prepuce The *Spirochaeta pallida* may be obtained not only from cervical erosions in the woman but from the secretions of the cervical canal. Long capillary tubes should be employed. Difficultly accessible deep lesions may be aspirated with the so-called "tonsil anesthetizing needle" with its Luer extension.

Lymph Node Aspiration.—Schaudinn and Hoffmann in their original communications describe the extremely valuable method of obtaining lymph node juices from adjacent enlarged nodes by syringe and needle aspirations To this technic has been added by Schultz and Sutton that of injecting a drop or two of physiologic saline solution and reaspirating it from the gland tissue or of distilled water used for the same purpose the purpose being to secure a certain amount of lysis of red blood cells. The great advantage of

such a method in dealing with lesions on contaminated surfaces such as the mucosae is in the fact that no pseudopallida organism has ever been recognized in the lymph nodes, so that the demonstration of spirochetes in lymph node juices is tantamount to a diagnosis of syphilis, and has medicolegal value. The technic of examination used at the University of Pennsylvania clinic is as follows:

1. Use rubber gloves.

2. A 3 cc. Sana-lok syringe, a 1½ inch 21 gauge needle, sterile saline and an alcohol sponge are needed. The needle and syringe are sterilized by boiling, the syringe is rinsed out with a small amount of saline, which is completely expelled and the needle is then attached.

3. The skin over the enlarged lymph node is rubbed vigorously with 70 per cent alcohol, and this is allowed to dry. The lymph node is identified and firmly held by the left hand between the thumb on one side and the index finger and ring finger on the other along its long axis. The Sana-lok syringe is held in the right hand with plunger in the "expelled" position. The needle is introduced along the long axis of the lymph node, about ½ inch to the right, and is then plunged into the body of the lymph node. One can be sure that the needle is in the lymph node by manipulating the syringe with the right hand and noting movement of the lymph node.

4. Immediately after penetration of the lymph node suction is employed by withdrawing the plunger of the syringe and the needle is rapidly plunged in various directions throughout the lymph node now firmly held by the left hand. This operation can be completed within 10 seconds.

5. The material obtained is usually milky and should not be too blood tinged. As a rule, enough fluid is obtained for 3 or 4 preparations, which can be examined by darkfield. A satisfactory specimen should contain at least 10 and *preferably more lymphocytes per high power field*.

While the number of organisms may be small, the identification of *Spirochaeta pallida* in the lymph nodes was accomplished by this method in nineteen of twenty cases of early syphilis.

Scrapings from the Umbilical Cord.—Ingraham (1935) used a 3-inch piece of fresh cord (portion nearest the child) kept in moist bottle and examined within eight hours using the middle inch splitting the single vein and scraping the lining after removing blood. Two preparations, ½ hour search. Often positive with negative cord blood serology.

Darkfield Examination of Pus.—Friedman (1939) at the University of Pennsylvania under Beerman's supervision developed a capillary tube method with centrifugation at 1000 revolutions which was successfully applied to the examination of urethral gonorrheal pus with three positives in forty cases and positives in other bloody and purulent material. The organisms are found at the junction of the sediment and supernatant serum.

Differentiation of the Spirochaeta Pallida and Artefacts as Seen in Darkfield.—The description of the living *Spirochaeta pallida*, verbal accounts of its differential morphology should not leave too unfavorable impression of the difficulties encountered in identifying the organism. None the less, there can be no denying that experience is essential in necrotic lesions, sometimes even after thorough cleaning, in lesions within the mouth and throat; and in foul cond lomas. Of the mouth spirochetes, *Spirochaeta microdentium*, while quite regular in shape, is only about half as long and half as thick as the *Spirochaeta pallida*, and consequently appears more minute. It may, however, in the longer forms, be almost indistinguishable except by its deep bluish staining with Giemsa. The coarse, large, very actively motile spirochete of Vincent's angina cannot possibly be confused with the *Spirochaeta pallida*. The spiral of the *Spirochaeta*

refringens is coarser with fewer less rigid and more regular turns. The movements are more rapid than those of *Spirochaeta pallida* and it does not keep its shape so well. The habitat of the *Spirochaeta refringens* indicates the means of practically eliminating it from the differential diagnosis by thorough cleansing of the lesion and the obtaining of organisms only from exuded serum. While in lesions within the mouth, surface material must be passed on by an expert, lesions on the lips seem less contaminated with adventitious saprophytes.

Once the student has clearly seen the highly distinctive characteristics of the *Spirochaeta pallida* he rapidly gains facility and trustworthiness in diagnosis. The spiral is of a peculiar brilliancy rigidity and regularity which is retained whether the organism is in motion or at rest and which suggests more than anything else as seen in the darkfield the rigidity of a steel shaving, and the brilliancy of a lamp filament. While the organism drifts with currents in the field its intrinsic movements are the slowest of all the spirochetes with which it is likely to be confused Other spirochetes are more *translucent, they collapse distort while in motion and squeeze into threads* between apposed objects in the field—but the *Spirochaeta pallida* "keeps its twist. It is, in the phrase so often used by Warthin, the organism "with waxed moustaches par excellence

Certain artefacts in the darkfield have caused inexperienced observers a good deal of difficulty at times. The commonest of these is the fibrin spiral, a waving bit of fibrin, often crinkled and attached at one end, which lacks the sharp clear-cut, spiral contour It wrinkles and is much finer and less refractile than the *Spirochaeta pallida*. Its attachment to the cover or slide can be readily detected by pressing lightly with an instrument point on the cover while the field is being watched. A second artefact, especially important in research work, is that described by Eberson as forming from red blood cells the carbon dioxide tension of the serum changes. We have occasionally seen these corpuscular rosettes in human blood serum and while no trained observer should misinterpret them, they may at times confuse the beginner into believing they represent clumped spirochetes

DEFERRED DARKFIELD EXAMINATION

Deferred darkfield examination by which is meant the examination at periods ranging from twenty four hours to several days after their collection of specimens of serum from suspected syphilitic lesions, is a procedure practically unknown in this country but one with many possibilities of development. It is not proposed that this technic of making an early darkfield diagnosis shall be regarded as superior to the direct examination of the patient. It has none the less a sufficiently high degree of applicability to have led the British Venereal Disease Service to adopt it as a practical device and a number of American State Laboratories, including those of New York and Pennsylvania, have made available mailing kits conforming essentially to the specifications of Mahoney and Bryant of the United States Public Health Service (Fig. 20)

Riehl, in 1919 and coincidently Scherreschewsky using glass capillary pipettes sealed by fusing in flame, first demonstrated the practicability of this method. Riehl found recognizable *Spirochaeta pallida* as long as fourteen days after collection W. H. Stokes and Leroy Ewing, in 1925, described an outfit for physicians to collect serum for darkfield examination. Mahoney and Bryant used fine straight capillary pipettes about 8 cm. in length and of constant bore. Harrison (1934) found *Sp. pallida* motile after eighty-four days in capillary tubes after having been shipped across the Atlantic four times.

The serum is collected from lesions as previously described, and the fine glass tubes (Fig 20) are filled by capillary action The ends of the tubes are then closed by pressing them into the soft paraffine vaseline mixture in the

small bottle for a distance of about 1 cm Serum containing *Spirochaeta pallida* secured both from experimental animals and from human cases of primary syphilis when thus sealed appears to support the organism in a viable and

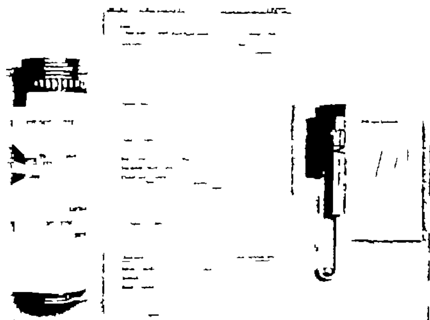

Fig 20 —The mailing kit for collecting material for darkfield examination, supplied to practitioners by the New York Stat Department of Health It consist of glass capillary tubes corked test-tube container small bottle of wax for sealing the capillary tubes mailing case nd instructions

entirely recognizable state for a considerable period of time While refrigerator storage yielded the best preparations good results were obtained in specimen kept at room temperature. Incubator specimens rapidly became unsatisfactory Motility progressively declined in twenty four to forty-eight hour

specimens but seemed to be confined chiefly to the larger motions, as bending and progression Distinctly motile forms were observed however at ninety six and one hundred and twenty hours and even longer Entirely recognizable forms were observed in one ice-box preparation thirteen days after collection

Fig. 11.—*Treponema microdentium* from the mouth Darkfield, × 1000. (Collection of Dr Noguchi.)

of the specimen Mahoney and Bryant give it as their opinion that the liability to error or faulty diagnosis does not seem to be great when the work is in the hands of an experienced microscopist, skilled in darkfield work. Modern equipment greatly facilitates the work.

Fig. 12.—*Treponema macrodentium* from the mouth. Appearance of young forms Darkfield × 1000 (Collection of Dr Noguchi)

The Paramount Value of Darkfield Diagnosis.—The most urgent need in the utilization of the darkfield in early diagnosis is an appreciation by physicians of its tremendous importance While this will be reemphasized in the clinical chapters, it is not out of place here to point out that while blood for a

serological test should be taken at the first visit, the use of the positive blood test for the identification of the syphilitic primary lesion on which with little trouble, an earlier darkfield examination might be obtained is unpardonable. It perpetuates an infectious focus and it loses the patient from 25 to 35 per

Fig. 24.—*Treponema genitalis* from smegma. Darkfield × 1000 (Collection of Dr. Noguchi.)

cent of his chance for complete and lasting cure. An untreated lesion is extremely important though not absolutely indispensable to a satisfactory examination. All educational campaigns and antivenereal movements should stress this fact and fight the tendency to self medication, drugstore prescrib-

Fig. 25.—*Spironema refringens* (culture). Darkfield, × 1000. (Collection of Dr. Noguchi.)

ing and oldtime casual doctoring (indiscriminate cautery, dusting powders and so forth) which defeat effective darkfield work.

The Securing of Darkfield Examination in Ordinary Practice.—Every practicing physician should be in touch with a hospital pathologist or a venereological specialist or a diagnostic laboratory of whose equipment and

expertness he is personally sure From them he should obtain cooperation for darkfield examination which he may not himself be equipped to perform The larger city health authorities are establishing darkfield stations in connection with other local laboratory facilities and clinics The physician should

Fig. 26.—*Treponema calligyrum* from smegma Darkfield × 1000 (Collection of Dr Noguchi.)

if possible accompany the patient to the specialist or send someone with him who will see that he gets there. No deferred darkfield examination can take the place of the personal conference between physician and specialist both as to diagnosis and treatment, or the value of the specialist's clinical examination

Fig. 27 —*Treponema cuniculi* from venereal lesion of the rabbit Darkfield × 1000 (Collection of Dr Noguchi)

tion in addition to the darkfield Node and lesion aspirations can in the present state of knowledge be secured only in this way The highest efficiency in the darkfield examination occurs within the first two weeks of the primary lesion and an even shorter period for more superficial lesions The shorter the

duration of the lesion prior to examination (i e., the fresher) the more significant a negative finding but no negative darkfield examination in and of itself even if repeated fully eliminates syphilis from the diagnosis All negative darkfield examinations should be followed by serological tests and serological follow-up as described on page 520

Stains and Tissue Methods for Identifying Spirochaeta Pallida

Staining methods for *Spirochaeta pallida* have increased so in number and amplification in the past decade, and reported superiorities are so far unconfirmed that a bibliography of recent technics is offered. Their common but inevitable disadvantage is the lack of the living form and movement of the organism

For details of technic of the following methods see the second edition of this work

Noguchi-Tilden buffer solution method; The Fontana-Tribondeau and Fontana arsphenamine-silver method *Levaditi silver reduction method Warthin-Starry stain for section work*

Some additional methods and modifications for smears and tissues have been recently proposed as follows

CHAPTER IV

SEROLOGICAL TESTS ON BLOOD AND SPINAL FLUID

The Mechanism of Serological Tests. The life history of serodiagnostic procedure in modern syphilology like the history of the discovery of the *Spirochaeta pallida* contains the unmistakable hallmarks of drama.

Bordet, in 1898 first clearly described serum hemolysis in the test tube. The half century since elapsed has seen the struggle between clinical and laboratory interpretation, the battle of clinical syphilologist and laboratory serologist for supremacy; the war between specificity and sensitivity in the tests themselves; the slow and difficult development of control in the older test, whole lifetimes of labor bestowed upon the perfection of the complement fixation procedure; and finally the rapid rise of flocculation methods with their lessened expense and increasing accuracy and the impending triumph of simplification in precipitation. The past ten years have been marked by international and of late especially American national comparison for purposes of standardization of a limited number of test and the development of mechanisms for the control of accuracy of laboratory performance. The nature of the syphilitic reagin, its presence in normal individuals its relation to the mechanisms of agglutination and antibody formation and its presence in normal individuals are under investigation. The positive serologic test has succeeded the negative as an object of challenge and investigation, and the biologic false positive, long regarded as a rarity has proven to be a significant factor in everyday diagnostic interpretation. Methods for the differentiation of biologically true and false positives are the chief immediate concern both of clinicians and serologists, today.

Fig. 28

MECHANISM OF THE WASSERMANN TEST

1. **Based upon the Bordet-Gengou phenomenon of fixation of complement.**
2. **Five distinct substances used, interacting in two groups, called the antigenic and the hemolytic systems.**
3. The hemolytic system is an indicator of what has happened in the antigenic system.
4. *The test may be performed on the blood-serum after removal of cells, on the spinal* fluid, extracts and secretions of syphilitic or other tissues, exudates and transudates.
5. **The five elements entering into the reactions are**

Complement, a chemical substance present in normal and pathologic blood in man and animals. It can be destroyed by heating to 56° C and when thus destroyed the serum is said to be "inactivated," and complement from another source must be added before the Wassermann reaction can be carried out.

Syphilitic amboceptor a substance which appears in the blood as a result of syphilitic infection, and which is not destroyed by heat. This element and complement form the reacting part of the syphilitic patient's serum.

Syphilitic antigen, extracted from syphilitic and certain other tissues and added to the serum for the purpose of binding the complement through the intermediation of the syphilitic amboceptor. The union between these three substances is indissoluble and when quantitatively carried out results in the "binding" or "fixation" of the complement, so that it cannot participate in the subsequent hemolytic indicator reaction.

Red blood-cells, obtained usually from sheep or man, washed and used quantitatively in a physiologic saline suspension. The lysis of these red blood-cells by their union with any unbound complement through the intermediation of the *hemolytic amboceptor* that indicates a "negative" Wassermann reaction.

Hemolytic amboceptor, which is obtained by immunizing a laboratory animal, usually a rabbit or dog, against the red blood-cells of sheep or man. When these red blood-cells are injected into the animal, the animal develops a specific hemolytic amboceptor which, combining with the normal complement of serum, produces hemolysis of the injected red blood-cells within the animal body. This reaction can be transferred to the test-tube by using the animal serum with a supply of the corresponding red blood-cells (4 to serve as an indicator for the presence of unfixed or unbound complement in the Wassermann reaction.

Both because it is historically the older procedure and because once its mechanism is clearly envisaged the strength and weaknesses of serological procedure in the diagnosis of syphilis become almost *ipso facto* understandable Figs. 28 and 29 first set forth the mechanism of the Wassermann test itself

All precipitation tests as now used are essentially equivalent to the antigenic system of the Wassermann reaction minus the complement with of course important technical modifications, the results being read direct. The

Fig 29

MECHANISM OF THE WASSERMANN TEST

The Antigenic System

1 *Complement* present in the patient's serum or if this has been inactivated, added in the form of *guinea-pig complement*
2. *Syphilitic amboceptor* also present in the patient's serum if the patient has syphilis, but *absent if he has not*
3. *Syphilitic antigen*, added to the serum in an amount proportional to the amount of complement known to be present, so that complete fixation will occur if the requisite amount of syphilitic amboceptor is present.

The mixture of these reagents is subjected to incubation or refrigeration, or both. If syphilitic amboceptor is present, the complement is fixed to the antigen, and the serum becomes incapable of reacting to the subsequent addition of the hemolytic indicator system. If syphilitic amboceptor is not present, the complement remains free and can enter into the next reaction, as soon as the hemolytic amboceptor and red blood-cells are added. The second system is, therefore an indicator of what has happened in the first.

The Hemolytic System

1 Hemolytic amboceptor in known amount, consisting of the serum of the immunized animal
2. Suspension of red blood-cells in an amount to correspond to the complement originally present and to the amount of hemolytic amboceptor added.

The mixture of the two systems is again incubated at body temperature

If the patient has syphilis, all the free complement will have been fixed by combination with his syphilitic amboceptor and the added antigen, and none will be available for the hemolysis

A Total Absence of Hemolysis Therefore Means Syphilis is Present.

If the patient does not have syphilis, all the complement will remain free or unfixed, for participation in the hemolytic indicator reaction as soon as the second group of reagents is added, and complete hemolysis of the red blood-cells will take place

Thus "Negative" Hemolysis Means Positive Wassermann and Positive Hemolysis Means Negative Wassermann.

The degree of hemolysis which occurs is to some extent a measure of the intensity of the Wassermann reaction. The more hemolysis the weaker the reaction. The more accurate method of making quantitative estimations of the degree of positiveness, however consists in varying amounts of reagent used, and especially of the fluid or serum which is being tested. Strongly positive sera produce complete inhibition of hemolysis in very small amounts.

Remember that the Wassermann Test is Not Infallible.
Positive Wassermann Tests, Like Negatives, May be False Technically or Biologically

physical precipitate produced in the positive serum by the mixing of antigen and syphilitic amboceptor is read by a variety of devices ranging from direct vision in the Kahn and Hinton tests, for example to various photometric procedures, as in the Vernes, and by the microscopical study of the precipitated aggregate as in the Kline test. One of Kline's diagrams here reproduced (Fig 30) visibly portrays the difference in complexity to say nothing of simplicity in materials required between the standard Wassermann proce-

Fig. 31

TOPICAL SUMMARY OF SEROLOGIC PROGRESS SINCE 1932

1. Better comprehension of immune body and syphilitic reagin relations.
2. Light on the specificity of tests for syphilis by the use of a spirochetal antigen (the Reiter and other antigens).
3. The presence of syphilitic reagin demonstrated in apparently nonsyphilitic human and animal blood.
4. Development of methods (Lund) for identifying minute amounts of syphilitic reagin. An investigative method.
5. Use of reagin titration in diagnosis and treatment.
6. Emphasis on quantitative serologic technics.
7. Recognition of zone reactions as sources of nonagreement in same serologic test.
8. Passing of the provocative procedure.
9. Continued controversy on contradictory and conflicting serologic result.
10. Testing of specificity and use of ultrasensitive procedures (screen, presumptive, exclusion and elimination tests) to exclude syphilis from effective diagnosis.
11. Increasing demonstration of the margin of error of the positive serologic reaction—expanding field of biologic false positives.
12. Development of procedures for differentiation of syphilitic from nonsyphilitic positives—verification tests.
13. Standardization of American serologic laboratory practice—approved tests, approval status based on extensive cross-checks of laboratory performance. Results of conferences. Approved methods of reporting.
14. Rivalry between newer simplifications and approved or standard tests.
15. Development of state laboratory systems. National possibilities.
16. Mass serologic testing and routine use of a case-uncovering mechanism.
17. The enactment and influence of blood-testing laws.
18. Definition of blood test and infectiousness relationships.
19. Relation between reagin content of the blood of mother and newborn child.
20. Declining clinical importance of seroresistance (fixed positive).
21. Initiation of research into the nature of the syphilitic reagin by chemical and physical serum fractionation methods.

dures and one of the simplest and most accurate of the precipitation technics Important recent efforts to simplify and make more available the reagents employed in standard complement fixation procedure include control of preparation by the originators of tests, and for example the Flosdorf Mudd cryochem process of drying frozen guinea pig serum for preservation of complement.

FACTORS IN SEROLOGICAL TEST PERFORMANCE AND INTERPRETATION

Laboratory Aspects.—The use of serological tests in the diagnosis of syphilis requires a partnership between serologist and clinician in which neither party should permit his native enthusiasms to blind him to the functions, duties and critical prerogatives of the other The interrelations involved can usually be made clearer by considering the two sides of the problem to some extent separately and combining the conclusions in a summary of the place of serological tests in medical examination

Rôle of Equipment and Reagents.—Certain elements are common to both complement fixation and precipitation technics but the former type because of the added complexity of a hemolytic system, inevitably involves the larger possibilities of error The first and most important item in the performance of serological tests is the antigen, which is common to both types.

Antigen.—The original antigen used in the Wassermann test was an aqueous extract of syphilitic fetal liver Within short time it was found that alcoholic extracts were more satisfactory that the use of tissue containing spirochetes as the source of the antigen was not necessary and that very satisfactory antigens could also be made from alcoholic extracts of human beef or guinea-pig heart from which the gross fat had been removed. The active principles of antigens are lipoidal in character The antigen is the foundation of each test procedure and the precise instructions of the originator of the method must be followed to the letter in preparing this basic reagent Even with considerable effort, antigens made in other laboratories than that of the originator may differ for reasons not as yet understood, and it may be necessary at times to secure the personal assistance of the deviser of the method in preparing the first batch of antigen. So critical is this issue in certain procedures, such as the Vernes, that the originators of the method have felt it necessary t place the manufacture of their antigen in the hands of responsible technician and t urge all users to procure their supply from headquarters or uthorised distributors. The complexity and difficulty of control of the original Wassermann procedure led to divergences in the preparation of different antigens almost as numerous as the proponents of individual systems. Antigens in general are prepared by soaking the selected minced tissue in 95 per cent alcohol for some eeks Various tissues differ markedly in their antigenic properties and even individual organs of the same anatomical type as, for instance beef heart, vary as prepared from different specimens The titration and standardization of antigen preparations and the bringing of individual fractions up t normal antigenic strength by cholesterinization is an important part of the ground ork of all serological laboratory procedure Wassermann technic, with its almost innumerable modifications, as distinguished up to within the past half decade by multiplicity of antigens, of hich the alcoholic extract of syphilitic liver of human, beef and guinea-pig heart formed one group the antigens standardized or increased in sensitiveness by the use of cholesterol constituted second group and the acetone insoluble fraction antigen, of which Noguchi' was the prototype, constituted third group Each of these types has somewhat different reactivity in the Wassermann procedure and may yield somewhat different results on the same serum. Multiplicity of antigens in the performance of serological tests was therefore virtually necessity in order to provide cross checks p thus the test itself on the results obtained ith given serum.

Kline and his coworkers, Levy Wellman and Lankelma, have been notable in this country for their efforts to free the essential antigenic substance of many impurities and contaminants and t ascertain if possible something of its chemical structure. Important publications have appeared (1937 1940, 1941 1942) Pangborn (1942) has isolated pure phospholipid cardiolipin, which is essential for the reactivity of beef-heart antigens in the serologic test for syphilis. The theory of antigen formation and action is discussed ith extensive bibliography by Weil Bacteriologic *Reviews*, 5 223, 1941 See also *Ratcliff* J Lab and Clin Med 27 729 March, 1942

With the perfection of precipitation tests on the one hand and the introduction of an antigen like the Kolmer in which the factors of control have been covered by an extremely elaborate investigation over a period of years the necessity for multiple antigen tests has declined and few antigens now receiving support from individual laboratorians will survive the demise of their inventors. There will remain, for a period of years perhaps, two or three standard antigens used in a quantitative procedure and controlled by precipitation as distinguished from complement fixation technic.

Complement.—Complement previously obtained from normal guinea pigs, was subject to considerable variations dependent on the frequency of bleeding, feeding of animals and so forth. These have been largely overcome and complement has been made available in almost standard form by the process of lyophilization. The manufacturers warn that the titer of lyophilized complement should always be compared with the titer of fresh complement before use. Kolmer Richter and Lynch (1938) regarded lyophile complement kept at 4 degrees to 10 degrees C satisfactory for complement fixation tests for syphilis for ten to thirteen months. Boerner Flosdorf and Lukens (1941) have stabilized vacuum-dried complement from large pools so that its potency may be extended to over three years.

Other Reagents.—All other reagents used in serological tests must be subject to constant check. Their titer must be carefully determined at intervals and in the manner prescribed by the originator of the procedure used. Salt solution must be accurately made up, the pH of the salt solution, the use of tap water as against distilled water the temperatures of room and reagent at the time of preparation and mixing, all requiring attention among the factors of control.

Care of Glassware.—This detail, especially with respect to the removal of all grease from the glass and test tubes is an important element in laboratory work with the serological tests and technicians who are careless on this point cannot be trusted. We have personally seen several near disasters and prolonged inaccuracy traced to this factor especially in small laboratories.

Fixation Temperature, in the Complement Fixation Procedures Especially.—Ice-box (Jacobsthal) and ice-bath (Duke) temperatures materially increase the sensitiveness of complement fixation reactions without increasing the risk of false positive results. It is important to point out, however that uneven cooling in a rack of tubes, for example, dependent on position in a refrigerator may lead to serious degrees of false positiveness in certain tests in a batch. The method of refrigeration, like that of incubation, requires, therefore, careful supervision. The time required for incubation and refrigeration in the complement fixation test is one of the most serious elements of delay and gives the more recently devised precipitation procedures a marked advantage in the form of prompter reports. The observations of Kline and Kahn on the temperature factor in precipitation reactions especially as affecting specificity are currently important.

Hemolytic System, Active or Inactive Serum.—Questions involving these details of technic are still too controversial for the average physician to concern himself with them. In this country the Craig (Army) and Kolmer systems use an inactivated serum, and the Noguchi system uses an active serum. British Medical Research Council system, No. 1 official for the British Venereal Disease Service, uses inactivated serum. The Hecht Weinberg system uses an active serum. The Army and Noguchi systems are antihuman, the Kolmer British Medical Research Council No. 1 use an antisheep system. The earlier reports in the case histories of this text were from tests performed by Sanford's system, employing an antihuman hemolytic system and an active serum. The system employed by Keidel and Moore at Johns Hopkins, on which many important publications have been based, uses an antisheep hemolytic system and an inactive serum.

Animals.—The condition of the animals used in complement fixation procedures is important. Too frequent bleeding alters the fragility of the red cells and Weyler has been able to demonstrate surprising variations in complement titer on guinea-pig blood by comparing the guinea-pigs which he used in London with those he used during the Second Serological Conference in Copenhagen, Denmark. It appears that feed may alter the characteristics of these biological reagents and accordingly one may expect variations in sensitivity and performance during summer compared with winter.

Collection of the Specimen.—Sticklers for exactitude may properly insist that blood be drawn from the patient before any ingestion of food for the day the theoretical ground for this stipulation being the possible excess of lipoid present in the blood after meals. The risk of false positives, in our experience, is not serious. But the point deserves consideration in ticklish cases. Craig and Nichols have shown that the ingestion of alcoholic liquors within twenty four hours before a complement fixation test may inhibit a positive reaction and render the serum negative to the Wassermann. In weak positive cases it is especially important to bear this fact in mind. Blood for serological tests must be aseptically drawn. Bacterial contamination of the blood specimen either through carelessness in drawing or through delay in testing a specimen markedly contaminated by improper shipment or storage is occasionally responsible for false positive results Craig points out, however that the degree of contamination and delay must be considerable so that this factor becomes operative only occasionally Stale sera are apt to be anticomplementary in the Kolmer test and are unsatisfactory for examination by technics using active serum or native complement. All specimens of blood for complement fixation tests should be handled under glass or cork seal since cotton fiber is said to produce changes leading to false positive results.

Wenger (1939) and Tulsky have called attention to the factors responsible for *hemolysis which causes the loss of many specimens whose examination is* delayed by mailing and so forth. Among these factors are distilled water in syringes, increased fragility and destruction of red cells by the use of force in ejecting blood from syringes (and possibly also in aspirating it from veins under marked suction)

Handling of the Specimen.—Much emphasis deserves to be laid on this point. There can be no question that even in the best laboratory practice *specimens are sometimes mislabeled, tubes are exchanged and erroneous* reports follow The practical details especially for the attention of nurses handling blood specimens, are given on pages 329 and 330

Anticomplementary Substances.—Unknown substances may be present or develop in serum on standing, which, because they destroy complement, produce false positive result (inhibition of hemolysis) in both serum and control Certain of these substances can be destroyed by heat but others cannot, and may make it impossible to perform Wassermann test on the serum thus affected. The occurrence of frequent anticomplementary reports in the work of laboratory is, in our experience evidence of a faulty technic and calls for investigation. The difficulty should be rare Flocks of anticomplementary reports usually appear when laboratory is testing out new method and we have heard it as the first objection offered to new system which was later accepted in its entirety without protest, when experience had done away with the technical difficulties

Technicians Technical Experience Serologists Interpretation.—The last ten years has seen a gradual recognition on the part of clinicians of the immense labor the constant vigilance, and the large element of experience which goes into the personal side of the performance of serological tests for syphilis. While the advent of precipitation procedure has unquestionably helped the situation materially it is a mistake to imagine that even the simplest of the precipitation procedures can be performed by any amateur anywhere, *at any time* without grave risk of error The clinician, compelled to interpret the results of laboratory tests by the touchstone of the clinical picture of the patient himself realizes perhaps even better than the serologist

how subject to revision and reinterpretation all statements particularly by the proponents of test procedures, must be held.

Just as animals in London differ from those in Copenhagen, antigens prepared in the originator laboratory differ slightly from those prepared elsewhere so must the interpretations of one laboratory differ from those of another It is impossible to dismiss the matter merely as difference in competence for both laboratories may take high rank on this score By a process of elimination, certain of these idiosyncratic variations can be seen, the result of experience to go back ultimately to the reputation and training of the serologist, his attitude toward the test, the technical make-up and changes in his staff, his clinical control and the irreducible false positive or relative positive-negative tendency of his laboratory

The serologic tests should not be performed as a side issue in small laboratories or by amateurs not under competent control The mastery of the mechanical technic is simple. The mastery of controls and possibilities of error the ability to find the source of trouble and the development of judgment in reading and interpretation of factors, is immensely difficult. Not every man who can gather the necessary bottles and test tubes is suited by training or temperament for the exercise of sound serological judgment. In the Copenhagen Conference of 1928, the absolute inevitability of false positives in the performance of the complement fixation type of test, even by masters of the art, was demonstrated beyond peradventure If as high as 14 per cent of false results could be obtained under such rigid conditions of control, it may be easily imagined that under less strictly regulated conditions there must be laboratories which are veritable mills of false positive reports, fastening suspicion of syphilitic infection right and left upon persons who do not have the disease. The newer types of procedure, in spite of their enormous increase in accuracy and dependability are not free from criticism on this score in spite of the infallibility with which the laboratory man is inclined, at times, to invest his favorite technic. Nor does the large laboratory giving a centralized service over a wide field of clinical pathology escape these difficulties. One of the most serious sources of error in larger laboratories is the changing about of technicians from one field of duty to another Dependable serological tests are produced year in and year out only by that form of adeptness which is developed by unbroken application to the work. Frequent false positives are the product of inexperience and overenthusiasm The amateur serologist himself approaches this problem too often with the attitude of a prosecuting attorney and boasts of his ability to prove a positive. False positives thus obtained are diagnostic malfeasances of the gravest type There are few laboratory procedures whose inevitable margin of error entails more social and personal suffering than the Wassermann reaction. Whatever savors of technical inexperience of the injudicious and uncritical temperament, of personal motive and purely commercial interest, of haste inaccuracy unpreparedness and pigheadedness, has no place in its performance The best results do not necessarily come from large establishments but rather from those in which personally skilful performance and supervision are available

In general, the serologist himself or a technician of years of experience only should read the results Inexperience at this particular point sends out broadcast flurries of false weak positives which may do inestimable harm, not only to the persons concerned as patients but to the confidence of the profession in the reaction In the same way a serologist temperamentally ultraconservative, by refusing to consider or report as *indeterminate* the partial positives he observes may materially reduce the efficiency of the test

Sensitivity vs. Specificity.—The physician who uses the serological tests for syphilis must clearly understand the rival claims involved in the title of this paragraph. Every advance in the sensitiveness of a serological test for syphilis—that is, in its ability to identify the disease in the absence of clinical signs—must be measured against the risk of pinning a partial or completely false positive finding upon a person who does not have the disease. It is proper therefore at the outset, to distrust the enthusiasm which recommends a new type of procedure or a pet hobby in the serological field as "highly sensitive." It is more important, for practical purposes, in our opinion that high *specificity* rather than sensitivity be accepted as the primary recommendation of a serological test procedure The more recent methods take careful account of both factors, as, for example, in the presumptive and diagnostic types of procedure recommended by Kahn and Kline for their respective precipitation tests. Kahn (1942, Serology) has pointed out that in 40 000 hospital admissions with 1200 cases of treated and untreated syphilis among them, an increase of 1 per cent in sensitivity means 12 cases of treated or untreated syphilis reported positive while 1 per cent increase in nonspecificity (loss in specificity) means 400 nonsyphilitic persons reported positive. By the older methods, specificity was weighed against sensitivity in the complement fixation reaction by the multiple antigens employed and highly cholesterinised antigens were ultimately very properly distrusted A part of this oversensitiveness can be controlled by using a highly sensitive test procedure for the initial examination so-called "screen test" of the serum, only the positives thereafter being subjected to the control of several methods of a less degree of sensitiveness. It has been considered proper to apply highly sensitive methods of testing to the serum of known syphilitic patients under treatment, in order to detect the slightest degree of positiveness as a guide to continuance

The efforts of Eagle to increase enormously the sensitiveness of serological tests will probably find their best application in this field rather than in that of diagnosis, although it has been the hope of certain investigators (Hinton) as yet unestablished that such combination of sensitivity and specificity might ultimately be obtained as to permit of the complete disappearance from clinical practice of that perplexing and disturbing combination, the negative blood and the abnormal or positive spinal fluid Kahn points out that limitless sensitivity is an inherent capacity of serologic tests, controllable by technical means including temperature conditions, etc. and that by appropriate steps, nearly all persons can be shown to give positive reactions for syphilis. In reading the literature, therefore, the practicing physician, particularly if he has power to influence a technician or laboratory should interpret with great conservatism all claims to high sensitivity unless they are accompanied by unescapable evidence of an equally high degree of specificity

Immune Body and Syphilitic Reagin Relations.—The original conception of the Wassermann reaction was that of a specific antigen-antibody reaction Many attempts have been made to reconcile the nonspecific reactivity of tissue lipoids employed as antigens and the conception of spirochetal products as the actual specific antigenic substances in serologic tests for syphilis Opinion, influenced by the work of Sachs, Klopstock and Weil (1925) leaned for a time towards nonspecificity of the antigen. Recent studies of Beck (1939) Kolmer and his associates (1941, 1942) and Eagle and his associates (1940) have tended to indicate that serologic tests for syphilis do partake of the nature of an immune body antigenic reaction, but the degree of specificity involved still remains a matter of dispute. The work initiated and stimulated by Gaehtgens (1929) who employed a special spirochetal antigen ("palligen")

a phenolized salt suspension of the so-called Reiter strain of alleged *Spirochaeta pallida* has been carried forward separately by Kolmer and by Eagle with strong indications that this particular spirochetal strain (and also the Kazan strain) has high specificity Eagle and Hogan are inclined to accept this rather high degree of specificity as distinctly due to a syphilis spirochetal antigen-antibody reaction. Kolmer and his coworkers seem more disposed to regard the reaction as in part due to natural group spirochetal antibody contained in human and in some animal blood which as well as that produced in syphilis, reacts not only with cultivated *Spirochaeta pallida* but with *Spirochaeta macrodentium Spirochaeta microdentium* and other spirochetes This spirochetal complement fixing antibody is increased in syphilis, malaria and leprosy and under the conditions, Kolmer believes, it is improbable that the spirochetal complement-fixation test will identify as biologic false reactions the positive Wassermann and flocculation reactions observed in nonsyphilitic persons with leprosy and malaria.

Specificity of Tests in the Light of Spirochetal Antigen Studies.—Kolmer and his coworkers believe that syphilitic antibody is distinct from the syphilitic reagin. Eagle and Hogan have thus far insisted that the two are probably identical. One point at which this difference of opinion would seem to be subject to test concerns the incidence of false positive reactions in diseases in which an abnormally high proportion of these reactions for syphilis is known to occur Thus lower specificity of the spirochetal antigen complement fixation reaction on the blood resulted in the Washington Serology Conference (1941) as compared with a number of the standard flocculation and complement fixation tests used in the serodiagnosis of syphilis. But in the cerebrospinal fluid where there is little or no natural spirochetal complement fixing antibody (Kolmer) the spirochetal antigen tests gave a high degree of specificity It would seem to the clinical mind that a type of reaction giving lower specificity with a supposedly more highly specific mechanism would be almost a contradiction in terms. The Kolmer conception, allowing for variation introduced by group spirochetal antigens and the separate identity of reagin and syphilitic immune body would be the more logical alternative.

Syphilitic Reagin in Normal and Apparently Nonsyphilitic Human Blood and in Animal Blood.—Increasingly critical examination of the mechanism of serologic tests for syphilis has shown as already indicated that on the one hand serologic tests can be made so sensitive that all persons will yield positive results on the blood serum and on the other that the serum of many persons apparently normal and of persons the victims of other infections and conditions may show measurable and even highly significant amounts of syphilitic reagin responsible for biologic false positive reactions. That the serum of a number of animals gives in varying percentages, positive results to serologic tests for syphilis even though the animals are known to be incapable of inoculation with the disease, should not, as Kemp Fitzgerald and Shepherd (1940) have indicated be regarded as an evidence of unreliability of serologic tests for syphilis in man. Many observers, including Kolmer Eagle, Kemp and Chesney have shown that complement fixation technics can be so modified for example, that they are always negative in nonsyphilitic rabbits and regularly positive at the height of the infection in syphilitic rabbits, notwithstanding the fact that a certain proportion of rabbit sera react positively to complement fixation tests for syphilitic reagin under certain modifications of technic. The whole subject of positive serologic reactions

for syphilis in animals is well reviewed by the above-named authors Kemp Fitzgerald and Shepherd.

In 1931 Malloy and Kahn succeeded in showing that when normal serum is mixed with standard Kahn antigen microscopic aggregates gradually form They were able to establish quantitative relations between the areas of aggregation developed during various periods of exposure for normal sera, and for syphilitic sera mixed with a standard and a sensitized Kahn antigen as used in the Kahn presumptive test. As the authors put it, "It appears that the difference between nonsyphilitic and syphilitic serum is one of degree rather than of kind that it is quantitative rather than qualitative. What occurs in syphilis is the increase of a lipoid aggregating quality possessed nonetheless even by nonsyphilitic sera. Pierce and Breazeale (1942) summarize experiments with plant saps and adsorbents such as calcium and sodium zeolite in which they find evidence that "reagin" is a divalent sodium or magnesium cation participating in a base exchange reaction. The beef heart antigen acts as a zeolite in producing a floc. The work is as yet unconfirmed. Schreus and Foerster (1934) Barnett, Jones and Kulchar (1935) devised methods and accomplished the demonstration of syphilitic reagin present even in the sera of nonsyphilitic individuals. These observations have been confirmed and Eagle, in an elaborately conducted and controlled survey of 40,545 students sera, estimated the incidence of one false positive reactor in every 1125 students as the probable normal for the biologic false positive Statistically corrected for other considerations, this proportion fell to one in every 4000 persons tested Mohr Moore and Eagle (1941) in the second and third papers of a series, have concentrated increasing attention by case studies and otherwise on the problem of biologic false positives, indicating particularly its close association with febrile infections, both of known and unknown character More detailed consideration of this problem is given below

Methods for Identifying Minute Amounts of Syphilitic Reagin.—Lund (1942) has developed as an offshoot of a medicolegal technic for the demonstration of agglutinins in dried blood stains, a centrifugalization procedure for the concentration of minute amounts of syphilitic reagin in blood serum This method has as yet only investigative significance but may constitute an important approach to the study of the biologic false positive reactions in normal and abnormal persons

Daily Variation of Reagin Content of Syphilitic Serum—This has long been regarded as a basis for fluctuating and alternating positive and negative reactions in serial tests on syphilitic and nonsyphilitic individuals. If the work of Mohr and Smith (1940) is confirmed, a large part of this clinically recognized daily variation will have to be assigned to the category of technical rather than biological error or variability Mohr and Smith showed by collecting and freezing a series of sera that the variability in reaction as between individual successive specimens practically disappears when a series of frozen specimens is examined at one and the same time Daily variability in serologic results is the basis of the clinical repetition of serologic tests in the investigation of possible false positives and positive-negative conflicts (Wassermann positive series) It is probably also a leading factor in the provocative procedure to be presently mentioned.

Reagin Titration in Diagnosis and Treatment.—As an aspect of the increasing emphasis on quantitative procedure in serodiagnosis in the attempt

to arrive at greater accuracy note should be made of the increasing use of the arbitrary "reagin titer" system of estimating the actual concentration of syphilitic reagin in a serum as measured by the particular serologic method used Moore and Eagle (1941) wisely point out that reagin titer varies with the technic, and even in the unavoidable variations in day-to-day sensitivity investigated by Mohr and Smith It is accordingly essential in interpreting reagin "units" as reported by various laboratories including for example those of the New York State Department of Health to realize that they are significant only as basis for comparisons or estimations when compared with other results obtained by an identically similar testing technic. The question as to whether reagin titer should be reported with the result of a test is one for much discussion but we believe on the whole such reports are more confusing than helpful in routine diagnostic work. In watching the increasing concentration of reagin developed in the serum of the syphilitic child seronegative or only weakly positive at first, quantitation of this type however becomes of considerable clinical importance. This will be considered more fully under the diagnosis of congenital syphilis (see also Fig 49)

Moore and Eagle (1941) established the fact that titer determined by their technic in complement fixation tests varied from 0 to 1000 units of reagin In primary syphilis the mean titer was 104 5 plus or minus 15 74 units in secondary syphilis the mean titer was 179 0 plus or minus 7.54 units. In various aspects of late syphilis, mean titer varied from 21.5 to 41 1 units. Latent syphilis and tabes dorsalis gave significantly lower titers than other aspects of late syphilis. The reagin titer of the blood can be reduced by treatment with or without clinical improvement, is not an expression of the severity or gravity of the syphilitic infection in the individual patient. The authors believe the reagin titer to be definitely related to the numbers of organisms present in the tissues of the host. The authors conclude that a single quantitative test before treatment is of no diagnostic or prognostic importance Further investigations by Crosby and Campbell (1941) indicated that there is an apparent provocative effect in the second week of treatment of seronegative primary syphilis as gauged by reagin titer but that this does not develop in seropositive primary or early secondary syphilis, is probably more apparent than real. Race, sex and age do not demonstrably affect initial reagin titer or its response to treatment nor is it influenced by the presence or absence of spinal fluid abnormalities The coexistence of pregnancy in early syphilis is also without effect the same can be said of the season of the year (winter vs summer) In the study of the course of so-called "serologically fast" syphilis, reagin titration, while the ordinary test reveals consistently strong positives, may indicate declines ranging from as high as 200 to 800 to as low as 4 units by the twentieth serial examination.

Quantitative Serologic Testing of Blood and Spinal Fluid.—Answering the demands created by Kolmer's quantitative Wassermann, the majority of complement fixation and precipitation procedures used in the diagnosis of syphilis now have quantitative modifications dependent on the use of serial dilutions of serum for expressing the approximate strength of the reaction. Kahn (1939) gives a good summary of the various reasons why a quantitative test has value, which can be briefly summarized as follows In questionable cases it is assumed that high titers are of greater diagnostic significance than low titers. Quantitative tests are assumed to gauge to some extent the activity of the syphilitic infection Quantitation may assist ultimately in differentiat

as much nonspecificity and quantitative versus qualitative variability as the serologic test for syphilis. Such confusion can be resolved only by conference and cross-check, by agreement among authorities as to the most acceptable standard procedure, and by their repeated and determined evaluation and reevaluation under the supervision not only of the laboratory but of the syphilis clinic.

It is now an established fact that even when performed by the originators under seemingly [illegible] but at different times and in different places, the most dependable [illegible] serologic tests do not give uniform results either [illegible]. That this statement applies both to precipitation [illegible] tests; that complement fixation tests will [illegible] tests are negative, and the reverse; that multiple [illegible] type may give, when used "in battery," a confusing [illegible] from flat negatives to strongly positive [illegible] the fact that no single serologic test and no combination [illegible] in our present knowledge give the inquiring physician [illegible] verdict as to whether or not the blood specimen [illegible] reagin in sufficient amount to demonstrate [illegible]. After all, one familiar with the history [illegible] the diagnosis of syphilis, finds less matter for [illegible] incertitude than he would find in the demonstration [illegible] exact and unvaryingly uniform test. The present use [illegible] mingling complement fixation and precipitation [illegible] in the history of serologic diagnosis the use [illegible] variations in temperature, dilutions, complement, salt [illegible] ingredients which characterized the over-refined test procedure [illegible] ago. Today the laboratory either on its own initiative [illegible] pressure of syphilologic or general practitioner demands attempt [illegible] at least too much rather than too little. The result, as Moore and Eagle point out, is simply confusion thrice confounded. That serologists, syphilologists and practitioners all find themselves in such a dither over serologic test discord and nonconformities is essentially a tribute to our tendency to serologism, the disposition to diagnose syphilis by blood-tests. On the one hand, Schoch will insist on two different tests and endeavor to reconcile their variable results in conjunction with the general examination for syphilis, while Moore and Eagle will insist that even though the results of multiple tests be reported to the physician submitting the specimen, it is the business of the serologist to head his report by a final evaluation which represents the serologist's opinion as to the presumption established by the multiple tests' results. Between these two extremes all sorts of procedure exist. Substantial agreement has been reached as the result of international and national conferences on the following points:

1. Absolute uniformity among test results on a single specimen cannot be expected.

2. Precipitation tests should be supplemented by complement fixation procedure either performed routinely or available if the result of the precipitation test is doubtful.

3. In the opinion of [illegible] only five procedures are sufficiently well performed by a sufficient number of laboratories to deserve the title of "approved." These are the Kolmer Wassermann test, the Kahn, Eagle, Hinton and Kline precipitation procedures. While there is no bar advisable to the performance of other types of test, they should be regarded in the effort to provide dependable national serologic service as research procedures rather than practice procedures. If additional tests are performed by any laboratory they should be a matter for supplementary

to arrive at greater accuracy note should be made of the increasing use of the arbitrary "reagin titer" system of estimating the actual concentration of syphilitic reagin in a serum as measured by the particular serologic method used. Moore and Eagle (1941) wisely point out that reagin "titer varies with the technic, and even in the unavoidable variations in day-to-day sensitivity investigated by Mohr and Smith It is accordingly essential in interpreting reagin "units" as reported by various laboratories including for example those of the New York State Department of Health to realize that they are significant only as basis for comparisons or estimations when compared with other results obtained by an identically similar testing technic The question as to whether reagin titer should be reported with the result of a test is one for much discussion, but we believe on the whole such reports are more confusing than helpful in routine diagnostic work. In watching the increasing concentration of reagin developed in the serum of the syphilitic child seronegative or only weakly positive at first, quantitation of this type however becomes of considerable clinical importance This will be considered more fully under the diagnosis of congenital syphilis (see also Fig 43)

Moore and Eagle (1941) established the fact that titer determined by their technic in complement fixation tests varied from 0 to 1000 units of reagin In primary syphilis the mean titer was 104.3 plus or minus 13 74 units in secondary syphilis the mean titer was 170 6 plus or minus 7.54 units. In various aspects of late syphilis mean titer varied from 21.5 to 41 1 units. Latent syphilis and tabes dorsalis gave significantly lower titers than other aspects of late syphilis. The reagin titer of the blood can be reduced by treatment with or without clinical improvement, is not an expression of the severity or gravity of the syphilitic infection in the individual patient. The authors believe the reagin titer to be definitely related to the numbers of organisms present in the tissues of the host. The authors conclude that a single quantitative test before treatment is of no diagnostic or prognostic importance. Further investigations by Crosby and Campbell (1941) indicated that there is an apparent provocative effect in the second week of treatment of seronegative primary syphilis as gauged by reagin titer but that this does not develop in seropositive primary or early secondary syphilis, is probably more apparent than real. Race, sex and age do not demonstrably affect initial reagin titer or its response to treatment nor is it influenced by the presence or absence of spinal fluid abnormalities The coexistence of pregnancy in early syphilis is also without effect the same can be said of the season of the year (winter vs summer) In the study of the course of so-called "serologically fast syphilis, reagin titration while the ordinary test reveals consistently strong positives, may indicate declines ranging from as high as 200 to 800 to as low as 4 units by the twentieth serial examination.

Quantitative Serologic Testing of Blood and Spinal Fluid.—Answering the demands created by Kolmer's quantitative Wassermann the majority of complement fixation and precipitation procedures used in the diagnosis of syphilis now have quantitative modifications dependent on the use of serial dilutions of serum for expressing the approximate strength of the reaction Kahn (1939) gives a good summary of the various reasons why a quantitative test has value, which can be briefly summarized as follows In questionable cases it is assumed that high titers are of greater diagnostic significance than low titers Quantitative tests are assumed to gauge to some extent the activity of the syphilitic infection. Quantitation may assist ultimately in differentiat

ing the biologic false positives of leprosy malaria and infectious mononucleosis as well as other nonsyphilitic diseases from syphilis. Quantitative reactions may be helpful in estimating the effect of treatment, especially in latency and for measuring the relative effectiveness of differing methods of treatment. Quantitation may indicate the oncoming of relapse and of favorable response in serologically resistant or "fast" cases Kahn recognizes a provocative rise and subsequent drop in quantitative values when treatment is initiated. Such a rise may be used in the interpretation of a therapeutic test. Quantitative testing is of great importance in the diagnosis and therapy of neurosyphilis, as will appear in subsequent chapters since it is a part of the basis of prognostic grading employed in clinical work. Finally quantitation is of great value in recognizing the status of the new-born child of a syphilitic mother during the first few weeks of life

Of these various considerations we are disposed to place by far the greatest emphasis on quantitation in spinal fluid examinations and in the testing of the blood of the syphilitic or potentially syphilitic infant. In other aspects of syphilis particularly in gauging the effect of treatment in latency and in all other prognostic interpretation, quantitative serologic testing is as often unsatisfactory and untrustworthy as it is illuminating The systematic reporting of quantitative tests to the practicing physician is so generally a source of confusion and misinterpretation that except when specially requested, it should not be done. The attempt to use quantitation in serologic tests in serial tests, in interpreting the differences in results between differing laboratories and in attempting a provocative procedure is in the light of the most recent work a source of confusion and possible error rather than help The statement of Moore and Eagle that quantitative testing, to have significance must be performed consistently by the same laboratory in any one series of reports on a given case, must be borne in mind for quantitative testing as between different laboratories is a fertile source of misunderstanding and error As yet, no valid investigative basis exists for the use of quantitation in differentiation of biologic false positives from true syphilitic positives in doubtful cases The recommendation originally sponsored by the League of Nations Copenhagen conference in 1928 with reference to the form of reporting serologic tests in at most two or three grades of positiveness, has been even more closely drawn in recent practice. The original recommendation calls for reports of negative, plus-minus, one-plus and two-plus the last mentioned being *strongly positive* More recently the tendency has been to report for ordinary purposes in routine tests, either a definitive negative or a definitive positive If the positive is not definite it is not reported as plus-minus, weak positive one-plus or any similar designation, but by the use of the words "indeterminate-repeat. This reminds the physician that partial positives are difficult of interpretation or even uninterpretable and that safety first" calls for the repetition of the test procedure on a blood which gives less than a definitive positive reaction for syphilis. It may be said we believe, that serologists in general entertain the more positive convictions as to the validity of positive tests It is clinicians whose puzzling and difficult experiences with "fractionated" reports lead them to clamor for clear-cut positive or negative answers to their serologic questions and hesitate at weak positive " doubtful," and similar reactions Kolmer who developed what we believe to be the all-around most satisfactory quantitative complement fixation test for general use, himself insists that the designations "strongly positive and weakly positive

be retained For the expert, quantitation is an aid For the average practitioner it is more frequently a source of confusion or error

Zone Reactions as Sources of Confusion.—Eagle (1037) has excellently summarized the various types of zone reaction encountered in the serologic testing of certain serums, especially with the complement fixation procedure and occasionally in flocculation procedures (Wiener 1037 Greene and Breazeale 1030) in which lower dilutions of serum may give negative reactions while the high dilutions give positive results. A number of possible factors are involved and the problem is mainly one for technical interpretation by expert serologists

A negative reaction obtained with a screen, exclusion" or "presumptive" test on an actually positive specimen (Kline for example) is reported by Myers and Perry (1942) as a "prezone reaction observed in positive sera. It occurs to the extent of 0 0 per cent of routinely examined specimens.

Passing of the Provocative Procedure.—It is still conceded by a number of observers that a rise in the titer of syphilitic reagin occurs in syphilitics and in apparently normal persons, following the induction of antisyphilitic treatment, particularly with an arsenical. The increasing evidence of the presence of syphilitic reagin in the blood of normal persons its increase under nonspecific influences such as intercurrent infections its increase following the very procedures employed to cause its increase in syphilitic individuals and the demonstration that serial tests on any blood are subject to marked variation, especially in borderline degrees of positive serologic reactions for syphilis have all weakened confidence in the test to the point where it can no longer be recommended for general use as a diagnostic procedure. On the other hand, that a rise in reagin titer does occur as a species of Herxheimer like flare reaction in syphilis occasionally justifies the expert, thoroughly familiar with the interpretative pitfalls involved in using what might be called a provocative procedure as an aid in diagnosis A series of tests performed on successive days by quantitative technic may yield enough presumption of the presence of syphilis to help out in connection with other evidence A rise in the titer of reagin or increase in the strength of a positive on successive weeks, conjointly with the administration of weekly injections of a bismuth salt, is occasionally of assistance in a doubtful case The least trustworthy of the provocative procedures in our estimation at the present time is the one formerly recommended as standard namely the taking of successive blood specimens daily for a week, following a single injection of an arsphenamine. The factors of error here rise to such a degree of importance that the single injection arsphenamine provocative can no longer we believe, be recommended In addition, moreover the possibility of causing a harmful exacerbation of the infection (therapeutic shock) by the use of an arsphenamine in a diagnostic procedure of doubtful value still further weakens its justification Moore (1941 text) cites the work of Eagle, Mohr Hogan and Kemp in support of this last-mentioned viewpoint.

The Problem of Contradictory and Conflicting Serologic Results.—The progressive obscuring of the simple positive or negative statement desired by the average physician as the result of a serologic test for syphilis is an inevitability dependent on the steadily increasing number of modifications and improvements in serologic testing technics the conviction of authorities that their individual procedures have special merits and as can be seen from the foregoing discussion the confusion element inherent in a test that involves

as much nonspecificity and quantitative versus qualitative variability as the serologic test for syphilis. Such confusion can be resolved only by conference and cross-checks by agreement among authorities as to the most acceptable standard procedures and by their repeated and determined evaluation and reevaluation under the supervision not only of the laboratory but of the syphilis clinic.

It is now an established fact that even when performed by the originators under seemingly ideal conditions but at different times and in different places, the most dependable and widely accepted serologic tests do not give uniform results either as to specificity or sensitivity. That this statement applies both to precipitation and to complement fixation tests, that complement fixation tests will give positives when precipitation tests are negative and the reverse, that multiple methods and tests of either type may give, when used "in battery," a confusing burst of results ranging from flat negatives to strongly positive, is simply a demonstration of the fact that no single serologic test and no combination of serologic tests can in our present knowledge give the inquiring physician an absolutely definitive verdict as to whether or not the blood specimens tested contain syphilitic reagin in sufficient amount to demonstrate the presence of the disease. After all, one familiar with the history of serology and its relation to the diagnosis of syphilis, finds less matter for surprise in this inevitable incertitude than he would find in the demonstration of a single absolutely exact and unvaryingly uniform test. The present use of multiple-test procedures, mingling complement fixation and precipitation methods, simply replaces in the history of serologic diagnosis the use of multiple antigens, variations in temperature, dilutions, complement, salt solution and other ingredients which characterized the over-refined test procedures of a decade or more ago. Today the laboratory, either on its own initiative or under the pressure of syphilologic or general practitioner demands, attempts to provide at least too much rather than too little. The result, as Moore and Eagle point out, is simply confusion thrice confounded. That serologists, syphilologists and practitioners all find themselves in such a dither over serologic test discord and nonconformities is essentially a tribute to our tendency to "serologism," the disposition to diagnose syphilis by blood tests. On the one hand, Schoch will insist on two different tests and endeavor to reconcile their variable results in conjunction with the general examination for syphilis, while Moore and Eagle will insist that even though the result of multiple tests be reported to the physician submitting the specimen, it is the business of the serologist to head his report by a final evaluation which represents the serologist's opinion as to the presumption established by the multiple tests' results. Between these two extremes all sorts of procedure exist. Substantial agreement has been reached as the result of international and national conferences on the following points:

1. Absolute uniformity among test results on a single specimen cannot be expected.

2. *Precipitation tests should be supplemented by complement fixation procedure either* performed routinely or available if the result of the precipitation test is doubtful.

3. In this country at least, only five procedures are sufficiently well performed by a sufficient number of laboratories to deserve the title of "approved." These are the Kolmer Wassermann test, the Eagle, Kahn, Hinton and Kline precipitation procedures. While there is no bar advisable to the performance of other types of tests, they should be regarded in the effort to provide dependable national serologic service as research procedures rather than practice procedures. If additional tests are performed by any laboratory they should be a matter for supplementary

report and should not be admitted to the status of "approved" until their repeated evaluation in national serologic conferences establishes their distinctive superiority.

4. The specificity of serologic tests is in general more important than their sensitivity. *Specificity should be practically 100 per cent, and in laboratory grouping and approval status,* specificity rating below 99 per cent on 200 test specimens or 98 per cent on 100 specimens should lead to the temporary exclusion of the test from the approved list until such time as modification reestablishes a rating for it of 100 per cent. Sensitivity on the other hand—"an approved sensitivity rating shall be not more than 20 per cent below that of the control laboratory in cases of late or treated syphilis, and within 1 per cent of that of the control laboratory in cases of untreated and secondary syphilis."

For those interested in studying the range of variability of serologic tests on individual specimens or in mass testing, reference should be had to the studies of Shepler, Lyons and MacNeal (1928) (Arch. Dermat. & Syph. 18:748), who coined the term "serologic discord"; Pierce and coworkers (1938) (Am. J. Syph., Gonor. & Ven. Dis. 22:39); Crawford and Day (1939) (J.A.M.A. 113:1718); Moore and Eagle (1941) (J.A.M.A., 117:849); Hinrichsen (1941) (Supp. No. 14, Ven. Dis. Inform.); Hodel (1944) (Ven. Dis. Inform. 25:315); Kahn (1942) (Serology in Syphilis Control, Chapter X); Hinrichsen's admirable summary includes the condensation of the results of the successive American serologic test procedure evaluations as well as the League of Nations conferences.

Ultrasensitive Serologic Tests (Presumptive, Exclusion, Elimination and Screen Tests).—In the effort both to increase the certainty of detection of syphilitic reagin in significant amounts for the diagnosis of syphilis, to *exclude syphilis* from a diagnosis by serologic test, and to provide a shortened and less costly procedure as a preliminary to more elaborate serologic tests on selected specimens, a group of procedures, chiefly precipitation in character, has been built up. There is an undoubted utility in these supersensitive foreshortened procedures but simultaneously some very serious drawbacks. First, it should be insisted that there is literally no such thing as a test which will *exclude* syphilis from a diagnosis. The presumption based on the belief that minute amounts of syphilitic reagin are less significant than larger amounts may be established against syphilis, but an absolute exclusion is impossible on any serologic grounds alone. For this reason it has been several times emphasized that the term "screen" is preferable to "exclusion," and that the term "presumptive" admits into diagnostic appraisal a false emphasis on serologic test results which is constantly misused by the practicing physician in his strong predisposition to make a diagnosis of syphilis on serologic grounds whenever he is given the least opportunity to do so. The foreshortened and ultrasensitive tests have achieved a part of their popularity because like the substitution of precipitation procedure for complement fixation they make a "high positive showing on tested blood" possible as a demonstration of efficiency at minimal expense. (The point of view frankly so expressed in several letters from health and laboratory authorities.) Eagle in particular has expressed a belief with which we are in the main in accord that it is doubtful whether ultrasensitive procedure really shows anything trustworthy that the adequately performed original precipitation test could not have supplied. The disposition to boost the showing of positives in the work of the serologic laboratory by the selection of sensitive first-line tests is a regrettable form of bias in a procedure which, at best, can never wholly escape interpretative personal equations. If screen tests are to be employed the reexamination of doubtfuls and questioned positives or negatives should include a complement fixation procedure, preferably the Kolmer. Partial positives (except in treated cases) are not diagnostic, but rather interpretative and investigative material for specialists, and whether reported in titer

or in pluses, with or without the results of repetitions, should be distinctly understood to be of only limited significance. They should be referred to an experienced or even a syphilologic evaluator for interpretation if possible, and are dangerous sources of error when reported for diagnosis to the average doctor

It should then be a fundamental principle emphasized by Moore among others, that the results of presumptive tests should only be reported when negative, and never to the practicing physician when positive or partially positive The positives obtained in the laboratory should be immediately checked against standard procedures, and only the standard results reported. Moore further advises that the use of presumptive and exclusion tests be limited to (1) the serologic testing of donors for blood transfusion as an added safeguard for the prevention of transfusion syphilis (2) in syphilis clinics in which there is expert clinical interpretation, and (3) in following the results of treatment in patients definitely proved to have syphilis. Otherwise used, the presumptive test result reported as a routine invites a margin of error ranging from 2 per cent to nearly 9 per cent of false or nonspecific results in nonsyphilitic patients Because of zone reactions, even the screen tests have so significant a margin of error that it is questionable whether they should be used at all as trustworthy screen procedures except in case of emergency or special circumstances.

The Expanding Field of Biologic False Positive Reactions.—The clinical syphilologist of twenty years ago found himself obliged continually to impress upon the practicing physician the ubiquity and importance of the false negative serologic test in the presence of syphilis. The syphilologist of today has almost completely reversed the position. He finds himself confused by the uncertainties of the positive and loud in warning not to accept the single the partial or even the repeated positive blood test as final evidence of the presence of syphilis In a way the present position threatens the intelligent use of serologic tests for syphilis far more than did the doubt attaching to the negative. Inevitably faith in the positive is being undermined and with it, the tremendous positive efficiency and low margin of error of serologic test procedure for syphilis in the aggregate is momentarily submerged

Intralaboratory (Multiple Test) Interlaboratory and Laboratory-Clinic Control.—The modern serological laboratory has, sometimes reluctantly it must be confessed finally begun to yield to the pressure of growing knowledge and to accept intra and extra-laboratory and laboratory-clinic controls in its syphilis serodiagnostic work. But the path of the syphilologist determined to invade the sanctum of the laboratory potentate with his demand for checks, has been by no means an easy one. Few laboratories as yet feel themselves obliged to check a series of bloods periodically against the findings of another laboratory A larger proportion of laboratories now perform two test procedures, one complement fixation and one precipitation, as checks against each other The large majority of the smaller or independent laboratories and even some of the larger institutions in this country at least, perform only a Wassermann test or the particular precipitation test which has been devised by the serologist at the head of the laboratory A few laboratories lean over backward in the opposite direction by performing multiple procedures in the effort to insure to their clinicians a report which shall leave no stone unturned no furrow unopened in the serological diagnosis of their cases. The inevitable result, in this last group is expensive and unnecessary reduplication with

confused and conflicting reports that make the serological going for the average physician as difficult as that on foot over a plowed and rocky field. Very few laboratories indeed have available or show themselves disposed to submit to syphilis-clinic control. It will be an evidence of the advance of a broadly modern syphilology when our serological brothers accept the copartnership and final voice of the syphilis clinic in the ultimate interpretation of serological results.

The Control of Laboratory Results.—The items which require periodic investigation in the serological work of a laboratory are the *false negative tendency* of the laboratory, the *false positive tendency*, and the maximum positive efficiency.

The false negative tendency, or tendency to yield negatives instead of positives in syphilis, is checked either for a test or a group of test methods by the running of known syphilitic sera. Two technics within the same laboratory may be compared with each other in this way; but a more satisfactory comparison is that between two laboratories using identical sera with either the same or different procedures. On several occasions when we have been called on to cooperate in such checks, we have been astonished at the proportion of negative results obtained in undoubted syphilis by serologists who were entirely unaware of the trend of their methods. The increased sensitiveness of present-day procedure is however greatly reducing the false negative tendency. Such declines in efficiency are sometimes due to changes in technical staff without change of method, and may amount to as much as a decrease of 50 per cent in the number of positive reactions rendered over a period of six months.

A second method of testing for *false negative tendency* can be found in the repetition of tests on the same patient. If a patient's serum yields a strong positive on one day and a complete negative on a *fresh specimen* the next day, this may be within the bounds of fortuitous variation, though improbably so. But when on repetition in undoubted untreated syphilis, positives with the first test are returned as positives with the second test only once in seven times, the remaining six being reversals to negative, the procedure is probably insensitive.

A third method of checking *false negative tendency* and the sensitiveness of a laboratory's results, is by comparing the ratio of partial positives to strong positives over a period of time. A marked increase in the proportion of weak positives reported may, of course, mean an overdelicate test, but when the average incidence of strong positives from the laboratory over a period of several years is known, a decline in the number of strong positives and an increase in the proportion of weak positives means an insensitive technic. In one such examination of a laboratory's results, the proportion of weak to clear-cut positives changed in six months from a ratio of 1 : 5 to a ratio of 1 : 1.8, while the total incidence of all positives obtained fell from 8 per cent to 3.4 per cent of all tests made. These declines in efficiency may take place most insidiously, and without constant vigilance and the best cooperation of clinician and serologist, may create a most mistaken impression of the prevalence of syphilis in the clientele and be responsible for many errors of omission in diagnosis.

The False Positive Tendency.—The *false positive tendency* of a laboratory can be determined in part by a duplicate performance of tests on identical sera by different laboratories over a period of several weeks or months. This interlaboratory check, however, is uninterpretable unless a third party to the arrangement exists in the form of a competent syphilis clinic which provides the medical decision as to the weight of evidence for or against syphilis in the given case. Individual false positives can be picked up and in part verified as such, by repetition of the test, and this method the clinic perforce must apply in a good many cases where the evidence for or against, from the clinical side, is scanty or debatable.

One of the best controls of false positive tendency is the daily report sheet of the laboratory performing tests for a large number of clinicians and patients. The admirable cooperation of Sanford during Stokes's Mayo Clinic experience made possible in this way the detection of most of the inevitable false positives that occur in the work of every laboratory. On the report sheet

false positives show tendency to occur in clumps, and the identification of three or four as occurring in single small rack of tubes t once rouses suspicion, both in the laboratory and in the clinic.

It is a mistake to suppose that the controls established for the Wassermann test in the laboratory itself are adequate to prevent the occurrence of false positives and the writers believe that the same statement applies even to precipitation tests simultaneously performed for control purposes That is, both Wassermann and Kahn for example on a single serum may be reported positive or negative and yet the report be false The differentiation of biological from technical false positives, also essential to the interpretation of the results of a laboratory is discussed under the positive Wassermann test.

Maximum Positive Efficiency.—Every laboratory should be periodically checked for its maximum positive efficiency against the blood of known untreated acute secondary syphilis and untreated early but clearly defined general paresis. The blood in both these phases of the disease is so nearly universally positive that a laboratory whose test procedures yield less than 99 per cent (and some observers insist even on 100 per cent) positives in these two phases of the disease should be regarded as running insensitive procedures.

Appraising a Laboratory.—The general work of a serological laboratory can be appraised to some extent through observation of its way of meeting the various possible factors of error previously described Technicians on rotating or frequently changing service glassware cleaned in casual fashion, numerous or repeated anticomplementary reports, flocks of unexplainable weak positives repeated and striking but unsystematized differences between multiple antigens, all very properly arouse the suspicion of the clinician who must interpret laboratory results to the patient himself Laboratories performing single Wassermann tests, laboratories which in this day decline to introduce precipitation procedures, laboratories which render partial, unsatisfactory reports on spinal fluid examinations when the fluid supplied was fresh, free from blood and sufficient in quantity all fall within the twilight *zone of possible unreliability*

What the Serologist Is Entitled to.—In exchange for his response in this matter the serologist has an equal right to check and inquire into the quirks, prejudices, foibles and false trends of his clinical associate He should receive for testing a specimen drawn and handled in accordance with the technic already described If inactivation is employed in the laboratory serological technic this should be performed as soon as possible after the blood is drawn and refrigeration should be maintained both before and after inactivation. The quantity of blood should be not less than 5 nor more than 10 cc., labels should be legible, affixed immediately and held in place not only by paste but by rubber bands. The proper requisition form should be made out in legible fashion and accompany the tube to the laboratory Much injustice has been done serologists, particularly by isolated practitioners, in criticizing reports based on thoroughly unsatisfactory material submitted for examination.

A LIST OF SEROLOGIC TESTS FOR SYPHILIS

A. **Approved Serologic Tests** (American practice) See Supplement No. 11 Venereal Disease Information, 1940, for complete technics.

1. *Complement fixation technics*
   a. Kolmer Wassermann.
   b. Eagle-Wassermann.

2. *Flocculation technic* (standard):
    a. Kahn standard.
    b. Kline diagnostic.
    c. Eagle macroflocculation.
    d. Hinton.
3. *Screen flocculation* (supersensitive for special purposes):
    a. Kahn presumptive.
    b. Kline exclusion.

B. Some New and Old Tests (not fully evaluated or not generally used in American practice).

1. *Complement fixation technic:*
    a. Medical Research Council No. 1 (British Ministry of Health)—cholesterinized human heart extract—4-tube set-up, sheep cell hemolytic system, with variable amounts of complement.
    b. Boerner and Lukens (B. L.)—simplified test; chief difference from Eagle and Kolmer complement fixation tests: mixing of certain of the reagents in bulk and use of optimum doses of complement, hemolysin and antigen in place of units.
    c. Spirochetal (Gaehtgens "Palligen")—antigen from Reiter and Kazan strains of *Spirochaeta pallida*, usable especially on cerebrospinal fluid; specificity on blood not exceptional.
    d. United States Army Wassermann—hemolytic system, antihuman.
    e. New York State Department of Health—Wadsworth, Maltaner and Maltaner (1936)—quantitative; used since 1937.
    f. Hecht active complement fixation method.
2. *Flocculation technic:*
    a. Boerner-Jones-Lukens—microscopic and macroscopic; beef heart antigen prepared by simple technic, using acetone in preliminary extraction followed by ether alcohol extraction.
    b. Davies micromodification of Hinton—micromodification of the Hinton test.
    c. Mazzini—slide flocculation test based on use of beef heart and egg yolk extract in antigen.
    d. Laughlen—employs special modification of Kahn antigen (Kahn antigen plus cholesterol, scarlet red dye and balsam); colored reaction.
    Eagle microflocculation—micromodification of Eagle flocculation test, using 0.1 cc. serum; antigen from beef heart fortified with cholesterol and corn germ sterol.
    f. Meinicke—active instead of inactivated serum, horse heart extract diluted with alcohol to which balsam of Tolu and benzoic acid are added.
    g. Müller Clotting ("Ballungs")—alcoholic cholesterinized ox heart allowed to mature in thermostat. Uses inactivated serum.
    h. Ide—coloring method, alcoholic (95 per cent) extract of beef heart muscle containing 0.2 per cent cholesterin to 100 cc. of which are added 5 cc. of 5 per cent solution of gum benzoin, and 0.1 cc. each of 1 per cent alcoholic solution of crystal violet and azure II.
    i. Chediak—micro-test, employing a drop of dried blood.
    j. Strauss slide modification of Kahn and Eagle.
    k. Sachs-Georgi—direct flocculation of cholesterinized extract (ox). Two procedures: "lentochol" (slower) and "citochol" (more sensitive, less specific).
    l. Murata test (Sachs and Witebsky)—ring modification of Sachs-Georgi test.
    m. Sigma reaction—cholesterinized alcoholic extract of calf's heart.
    n. Vernes—elaborate test; special reagents and apparatus; read for day to day variation, uses horse heart in antigen.
    o. Leiboff—colored reaction.
    p. Levy—antigen mastic flocculation.
    q. Marquez (Rein-Hazay modification).
    Sellek—Frade II.
    s. Dyts.

C. "Verification" Tests

1. *Kahn* (temperature test) for differentiation of true from false positive reactions by performance of Kahn test at 1° C, 37° C and 57° C. (Not satisfactory test.)
2. *Kahn* (new) *salt concentration test*, specific and nonspecific serologic reactions are affected differently by certain concentrations of sodium chloride. (Not evaluated.)

D) Choice of serologic test for serum:

A survey of results obtained with the tests under consideration by the Washington Serologic Conferences (1935–1940) in all five of the evaluation studies in which they were used gave definite indications of the relative value of the different American tests. Only in the first evaluation study were the syphilitic patients classified as primary secondary and late syphilis. The Kahn presumptive the Hinton, and the Kline exclusion tests were the most sensitive tests in primary syphilis, giving 82.9 81.0, and 80.5 per cent of positive reactions, respectively the Kahn standard, the Kline diagnostic, the Eagle flocculation, and the Kolmer gave 79 7 74 4, and 72.1 and 63.9 per cent of positive reactions, respectively in primary syphilis. All of these tests were 100 per cent positive in secondary syphilis. In late syphilis the Hinton, Kahn presumptive, Kline exclusion, Eagle flocculation, Kahn standard, Kolmer and Kline diagnostic tests gave the following percentages of positive reactions, respectively: 84.5 84.5, 83.0, 82.4 76.9, 72.1 and 71.5. However sensitive test is valuable only if it is specific at the same time; in fact, specificity is much more important than extreme sensitivity if choice between the two characteristics has to be made. In the first evaluation study the Hinton gave 0.7 per cent of false positive reactions, the Kahn presumptive 3.3 per cent, the Kline exclusion 0 7 per cent, the Eagle flocculation 2 0 per cent of false positive reactions, the other tests having 100 per cent specificity In other words, the three most sensitive tests were also the most unreliable tests in this first study The tests hich gave false doubtful reactions in two or more of the four evaluation studies were the Hinton, Kline exclusion, Kahn presumptive, and Kline diagnostic tests. The Eagle complement fixation reaction as done only in the second, fourth and fifth studies in which it was 100 per cent specific. The most outstanding test in regard t specificity is the Kolmer test. In all 5 evaluation studies it was 100 per cent specific and gave even among the syphilitic serums only one doubtful reaction. In the first two studies its sensitivity was rather low in comparison, being 72.1 (late syphilis) and 59 0 per cent respectively However in the last three studies its sensitivity compares very favorably with that obtained with other tests which were less specific.

The Kahn presumptive and Kline exclusion tests are not specific enough to be used as diagnostic tests.

The flocculation procedures are inferior to complement fixation in testing spinal fluid.

E. Some Additional Principles

1 Frequent departure of users of test from the details of the originator methods, is common source of error
2. Short-cuts and obsolete technics are source of error
3. The control serologists (originators of principal tests) had only 4 false positives in 4 years. As of 1940, one fourth of the State laboratories were doing superior work. Thirty were doing unsatisfactory work in 1936, 22 in 1939
4. Two tests should be performed for the final evaluation of all specimens—either two of the same type (complement fixation or flocculation) or one of each type. A single test leads to errors. Technicians should receive basic training at laboratory control centers or originators laboratories, for the tests they are to perform.
5 The recommendation that plus marks be dropped in the reporting of serologic tests for syphilis, and that the words, "positive, doubtful, and "negative be used instead, first made at the League of Nations serologic conference at Copenhagen in 1923, was accepted and recommended for American procedure. The definition of doubtful" however continues to be matter of uncertainty and number of serologists (Wadsworth, Cannelmas) and syphilologists feel that some form of definition (reagin titer report, etc.) should be offered the physician to aid in interpreting this category

THE CLINICAL ASPECTS OF THE INTERPRETATION OF SEROLOGICAL TESTS

The Positive Serological Test.—There is inevitably a certain amount of overlap in the discussion of clinical as contrasted with laboratory problems in the interpretation of serological tests. At the same time it is worth while to give the clinical side some degree of special emphasis. The habit of accepting without dispute the report of a laboratory is so firmly impressed upon the present generation of physicians that it is necessary to drive home with more than ordinary force the statement that no serological laboratory no matter how well and conscientiously conducted is ever always right in its reports

Fig 34.

A SUMMARY OF LIMITATIONS AND POSSIBILITIES IN SEROLOGICAL TEST CONTROL (LABORATORY PHASE)

1 The Physician's desire for consistent 100 per cent specificity nd sensitivity and bsolutely clear-cut report cannot be met by any serological test or combination of tests for syphili in routine performance today Agreement on positive results in tests performed by groups of serologists ranges from 78 t 100 per cent.

2. Agreement between tests however is not tantamount t clinical accuracy

3. Disagreements must be expected:

a. Between antigens in the same W ssermann test

b. Bet een the results of two or more tests in the same laboratory on single serum. This is true sometimes even hen the tests are of markedly different type (as in kolmer W ssermann and kahn precipitation tests), or when they are similar (Eagle Hinton and Kline)

d When the same serum is tested in two different laboratories even by supposedly identical methods.

When the serum of lat and latent syphilis or yphilis in pregnancy is tested by any group of different method (serological discord)

f When the serum of the same patient is repeatedly tested by identical methods on successive days or t longer interval

g When treatment has intervened to lter the routine expectancy indicated in Figs. 38 t 41

4 Th frequency of disagreement and the margin of inevitable error diminishes ith the perfection of technical performance but it has never completely disappeared.

5 Essential elements in securing maximum reliability in performance by the laboratory are

A good specimen; stable experienced technical service cle glass fresh animal (Wassermann test) uniform expert reading conditions, voidance of the experimental in routine reports, a nonpartisan serologist; strict adherence t the originator technic and his modifications of his method.

b. Approved" laboratories { Intralaboratory check by multiple tests (but not too multiple) Interlaboratory exchanges of sera periodically for test purposes.

c. Laboratory-clinic check, against the opinion and experiences of syphilis clinic (state and cit laboratories should note, as well commercial groups).

6. Laboratory-syphilis clinic cooperation should include:

a. Daily report sheet of all tests done on the general hospital clientele, as ell those done for the syphilis clinic sent to the syphilologist for check against clinical diagnosis.

b. Complaisance on the part of the serologist in performing clinical check procedures (provocatives, series, presumptive nd diagnostic test)

c. Complaisance in the performance of laboratory check procedures (investigation of suspicious positives, decline in sensitiveness, false positive and negative tendency adoption of improved serological procedures or those thought likely t be improvements)

7 Laboratory-practitioner cooperation should include

a. No weak positive confusing or conflicting report to be made in first instanc except as undeterminate—repeat.

b. The exception—treated cases.

c. Adequate clean specimen properly labelled, ith proper data (type of syphilis or other condition; previous treatment)

This applies with equal force to complement fixat on and precipitation procedures.

The serologic tests for syphilis have recently been subjected to heroic reevaluation. Formerly used for the examination of the sick, and to large extent those m bom some suspicion of the need for it actuated the doing of the test, the negative result as first shown to have margin of unreliability that made t unable t stand alone or thout repeated confirmation by laboratory

and clinical examination. The positive, on the other hand, received a rising vote of confidence. The past five years, the era of the Wassermann barbecue and the wholesale application of serologic tests to large groups of the well, have now shown the positive serologic test, no matter by what method or how rigorously performed, to have a margin of nonspecificity of disturbing proportions. The presence of syphilitic reagin in normal persons; its rise and fall under drugs, diseases and unexplored factors; the uncertainty as to its whereabouts, mode of generation and actual nature; its absence in undoubted syphilis with characteristic manifestations; the anxious attempts to define by such methods as verification tests, so-called, by quantitative procedures, by spirochetal antigens, including even the Reiter strain whose superior specificity approaches the ludicrous, as we have seen, all these considerations and many more have given the thoughtful observer a real case of serojitters. Imagine the plight of the practitioner, the examiner passing on Selectees, and the syphilologist, as the list of diseases (Figure 33) known to be responsible for the appearance of reaginlike substances in the blood grows and grows, and the time after their occurrence in which false tests remain positive stretches from days to years. No longer is it possible to seek refuge behind the belief that mere over-sensitiveness of test procedure is responsible for the decline in reliability of the positive report. It is true that the wholesale use of screen tests, even the best recognized of which have their slippery edges, has led to confusion, not wholly corrected by the performance on positive serums, of one of the basically more stable procedures. The trouble lies deeper than that—as deep as our ignorance of the nature and identity of the syphilitic reagin and its congeners, and that ignorance is profound indeed.

The serious search for the substances suspected of being a serum protein or globulin fraction is now on, under the auspices of the National Research Council—supported investigation, armed with chemical fractionation of plasma or serum and with Tiselli—a word to conjure with. One might suggest that the reagin may turn out to be anything but a substance—rather a relationship or variable balance or proportion between substances or fractions or a mode of reaction to varying concentrations and electrolytic conditions. But whatever it is it must now be found if we are to filter out the dross from our years of confidence in serologic tests for syphilis. How shall the practitioner in the field identify the common sense of the matter and what common denominator for the situation shall we offer him? Let us attempt one.

The Clinical Compromise.—The blood test for syphilis has always been recognized as unfit to stand alone; it is a reproach to use it as a sole basis for treatment. It cannot decide either way the question of infectiousness, ever. There, then, goes much of its public health significance. In the absence of clinical signs of syphilis, it has at most discovered only latency. That and congenital infection are, at least as we have been observing it, overwhelmingly the harvest of its routine use to determine physical status and fitness anywhere. It is strongly, repeatedly and incontrovertibly positive by any reliable or so-called "standard" method of performance early in the disease, though not quite at the start. The see-saw of weak positives and conflicting laboratory and varying method reports has been shown, subject to confirmation, to be largely "technical" stuff (Mohr and Smith 1940). It is strongly positive, or there are strong positives in a series, in asymptomatic neurosyphilis as a rule. The relatively rare exceptions are, like late tabes, brain gumma, and so on, accompanied by diagnostic signs. Liver, spleen, bone, eye, gastro-intestinal tract lesions are apt to be inescapably positive. If they are not, something is seriously wrong with the laboratory. Syphilis most likely to escape a serologic uncovering mechanism, backed by a reasonably competent examination, is that of the pregnant woman and especially the multipara, and the early cases of syphilitic vascular and cardiovascular disease. The fluoroscopic examination of the heart and great vessels and a spinal fluid examination can prevent casual misinterpretations of serologic positives or negatives, whether they represent latency or progression in the large majority of cases.

The positive diagnosis of syphilis can, then, be made safe. Its elimination once the suspicion is aroused by a test, has always been difficult, and probably will long remain so. Certainly, even with our present armament of tests and

studies roentgen-ray and spinal fluid included one hesitates to tell a person who has chalked up a strong serologic suspicion or a woman who facing marriage and pregnancy has chalked up a weak one not to take treatment They had better be treated for life insurance

In practical terms it may be said that no patient should be given his diagnosis or placed on treatment on the strength of a single positive serological test any more than on the strength of a single negative one This statement implies that there must be false positive results and these are conveniently though somewhat arbitrarily classified into technical false positives and *biological false positives*. The former being errors introduced by the intrinsic qualities of the technic or the methods of the laboratory have already been sufficiently discussed The inevitable incidence of technical false positiveness in the work of good laboratories probably ranges between 0.1 and 1 per cent Repetition to control *technical false positives should* usually be made on fresh serum but if discovered in time the original serum may also be run again provided the quantity is sufficient a a control on the repetition.

Mailed specimens, hemolysis, age (over 4 days) lack of refrigeration, bacterial contamination, cotton stoppers, improperly cleaned glassware and tubes ... alkali and other factors (Kolmer and Brown) render results unreliable

The Biological False (Non-specific) Positive Serologic Reaction.—In Fig 33 we have attempted a classification of the occurrence of biologically false positive serological reactions for syphilis, summarized from the literature and from our own experience Much of the evidence in the literature is, of

Fig. 33.

DETAIL ON BIOLOGIC FALSE POSITIVE SEROLOGIC REACTIONS

Disease group	*Frequency (estimated)*	*Duration positive*
Normal persons	1 t 4000	Temporary or permanent
	Spirochetes	
Yaws.	100%.	Persistent.
Relapsing fever	5–40%.	1–6 weeks after temperature normal.
Rat-bite fever	0–30% or more spirillary form 37 % at eptobacillary form.	While febrile
Pinta	60% early 100% late	Persistent
Bejel.	70%	
Weil' disease	Occasionally mentioned	
Field fever	100%.	
Vincent fusospirillosis.	Occasionally mentioned.	

Fig. 33.—*Continued*

Disease group.	*Frequency (estimated)*	*Duration positive*
	Protozoal Infections	
Malaria.	100% t some stage	2–4 weeks, plus.
Kala-azar	"High.	
Cutaneous leishmaniasis.	Rarely—35 cases (11 positive; 18 negat ve; remainder variable)	
Trypanosomiasis.	Unsettled	
	Rickettsial Infections	
Typhus fever / Spotted fever	Frequent.	Frequent during fever disappear in convalescence
	Virus Infections	
Vaccinia.	10–35%.	Begin bout 12 days af ter vaccination, persist until 3–4 months after vaccination. Usually low titer
Chickenpox.	Occasional	
Mumps.	Occasional.	
Measles (also Rotheln)	Occasional	
Influenza	Frequency not know	
Some respiratory infections	Frequent	Few eeks.
Virus type pneumonia?	Frequency not known.	
Poliomyelitis	2 cases	
Lymphogranuloma venereum.	0–50%, 61% rectal stricture (false?)	Fluctuating
	Streptococcal Infections	
Hemolytic strep. infections.	3 cases.	2 12 eeks
Scarlet fever	0–0.6%.	Appea 20–25 days or after 35–48 days.
Septicemia / Endocarditis.	6 of 30 cases; 16 of 32 cases 2 cases.	
Acute pemphigus.	1 case.	

Fig. 33.—Continued

Disease group	Frequency (estimated)	Duration positive
Other Bacterial Infections		
Leprosy	60–80%	
Tuberculosis.	0–0.8 to 3.7%; infantile 5%	
Pneumonia.	Occasional, up to 5–40%	Transient to several months.
Diphtheria.		
Glanders.	Mentioned.	
Ulcus molle	Denied by some; 3 of 21 cases.	
Infections Cause Unknown		
Infectious mononucleosis.	2–20% 5–10% (Rein) 20–63% (Moore)	5 months.
Sore throat, no organism.	9 cases.	
Pulmonary	Occasional.	
Acute abdominal infections.	Occasional.	
Urogenital infections.	Occasional.	
Acute adenopathies.		
Dysentery Amoebic?	1 case 1 case	
Fever	2.2–8.9%.	
Acute lupus erythematosus.	Occasional.	
Sarcoidosis.	Occasional.	
Metabolic and Nutritional States		
Hyperproteinemia.	25%.	
Scurvy Purpura Acute malnutrition (infants) Cardiac disease Pellagra Beriberi	Isolated cases.	

Fig 33 —*Continued*

Disease group	*Frequency (estimated)*	*Duration positive.*
	Malignancy	
	1.6–9 7% 0–21.5% Standard tests nearly all 100% specific.	
Carcinoma of cervix.	14.1%.	
Leukemias.	Occasional	
Granuloma fungoides.	Occasional.	
	Drugs	
Arsphenamines.	Occasional.	
Lead poisoning	Occasional.	
Ether anesthesia narcotics, alcohol, paraldehyde etc.	About 20%.	Lasts up t 14 days.
Acetic acid poisoning.	Occasional	
	Miscellaneous	
Jaundice	2 0–3.9%.	
Pregnancy	0.5 to 1.9–3.8%.	
Epilepsy (?)		
Coronary thrombosis (?)		
Horse serum therapy (?)		
Cadaver blood Various diseases Psoriasis Pemphigus Aphthae (herpes) (see virus) Basedow disease Diabetes (?) Eclampsia Ulcus tropicum		
Menstrual blood (?)		

course dependent on individual cases, for extensive surveys are comparatively rare Certain conditions, notably frambesia, trypanosomiasis, ulcus tropicum and recurrent fever are comparatively rare within American territory or jurisdiction but will become more significant because of the war Admiral Stitt has pointed out that he *believes a part of the reported evidence*

for nonspecific positive Wassermann reactions in lepra comes from patients who have been cross-infected with yaws. Several illustrations are included among the case summaries in this chapter (Figs 31 35 30) There is not the slightest doubt in our minds that by the older Wassermann procedures and, on occasion, also by both the modernized Wassermann procedures and the precipitation tests, unquestionable nonspecific positives are obtained in chronic occult glandular tuberculosis, endocarditis subacute septicemic conditions and the cross fire of the two types of process which one observes occasionally in patients with "tuberculids" "septids" and the septic phase of disseminate erythematous lupus.

Fig. 31.

SEPTIC FOCUS? FEBRILE STATE, PROBABLE NONSPECIFIC POSITIVE SEROLOGICAL TESTS QUESTIONABLE EVIDENCE OF SYPHILIS

Youth, aged seventeen.

Chief Complaint Supposed acute appendicitis with fever hurried to hospital.
Routine Blood Wassermann Reaction by hospital laboratory no clinic control, strongly positi
Fever Subsid s, patient discharged, no operation.
Kolmer, 00, Kahn 014, four days after first bismuth injection, hile patient afebrile. Clinic-controlled laboratory
Immediate and Subsequently Repeated Tests, totally negative
History of running y from home t weeks t age fourteen. Denies exposure probably truthful.

Previous Bouts of Fever hes exerac ti e, recovers in bed.
Physical Examination Heavy clavicles, slightly rounded tibia, otherwise negative. Basal erosion, angle of mouth, disappears after first injection Bi. Mother serologically and superficially clinically negativ
One Year' Treatment, no change physically Serologically constantly and completely negative. Lapsed from observation.

Discussion

1 Improbable though not impossible that this patient has syphilis.
2 Unsupported single positive blood Wassermann reaction during febrile interlude not sufficient to make diagnosis.
3. Mouth erosion hile not suggestive in appearance might have had darkfield even then might have given erroneous findings.
4 Could the blood W ssermann reaction have been so completely reversed four days after half dose of B' if dealt syphilis? Probably not.
5 A prenatal infection or an acquired infection three years old ith mucosal relapse (previously untreated) ould almost certainly ha been more resistant serologically
6. This is probably therefore nonspecific positive blood W ssermann reaction associated with febrile period, cause unknown.

The True Positive Serological Reaction.—The preceding discussion of the pros and cons of positive serological results must not be allowed to dim the realization in the mind of the practitioner of the very high diagnostic value of the positive blood serological reaction. For this reason the person who has had a single unconfirmed positive Wassermann test must at least be enjoined to have the test repeated at some interval too short to permit of damage, and yet long enough to allow of a change in the complement-binding qualities of his serum.

Summaries of adequate procedure are given in Fig 57 and "The Clinical Compromise under Clinical Aspects

Fig. 35.

SEPTIC PEMPHIGUS? OR ACUTE DISSEMINATE LUPUS ERYTHEMATOSUS WITH BIOLOGICAL FALSE POSITIVE (NONSPECIFIC) SEROLOGICAL TESTS

Rabbi, aged thirty, married.

N Children, no miscarriages.
Examined 9/6/31
8/31 "Grippe."
Followed by profuse bullous eruption with crusting and erosions, face, scalp, chest, flexures. Multiple erosive mouth lesions. Papula axillary and perineal lesions.
Darkfield **Negative.**
N Fever
9/8/31 **BWR, Kolmer 44, Kahn 122, and Kline Positive.**
Extension of **Lesions**, no hoarseness.
BWR Three Weeks Later Kolmer *22*, *Kahn 122*, *Kline negative.*
Blood Count, slight leukopenia (4350 WBC)
N Clinical or Familial Evidence of syphilis, acquired or prenatal.
Bismuth and Bismuth Arsphenamine Sulphonate Intramuscularly N Effect.
10/31 **Extensive Severe Sepsis,** impetiginous, paronychial and whitlow lesions.
Fever to 103 F
No blood cultures (out of control)
Vegetative lesions ppea
10/31 **Death.** No autops

Discussion

1 This patient almost certainly did not have syphilis. The serological tests were done in conservative laboratory under clinic control.
2. This is probably clinical example of th septicemic (butcher's) type of pemphigus, though it also suggested the septic phase of acute lupus erythematosus.
3 It illustrates how septic process with fever may yield probably false positive results in both complement fixation and precipitation test for syphilis

Fig. 36.

FEBRILE PSEUDOSYPHILIS AND THE CONFLICTING SEROLOGICAL REPORT

Male, aged forty-eight, married.

Examined 11/13/28.
Wife and 2 children ell, no mortality
8/28 "Grippe, fever 100 t 101 F
Lump Below Jaw Supposed carbuncle (Had had t previously)
History of "Cut" by Barber no sequela
9/28 **Loss of Weight,** malaise
10/28 **BWR Positive,** *State laboratory*
BWR N gative, excellent privat labora tory
BWR Positive, on repetition by same private laboratory
10/28 ***Skin Eruption,*** *called purpura by internist.*
BWR Positive by Third Laboratory ith- out clinical control.
Systolic Aortic Murmur First Heard. No enlargement.
Widal, blood cultures negative.
11/28 **Patient Continues Mildly F brile.**
Treatment for Syphilis Begun with Neo.
Eruption Disappears.
Fever Continues, with occasional evening chills.
11/28 **General Health Improves.**
BWR Strongly Positive by Third Laboratory (as above) again obtained after sixth injection Neo.
BWR Kolmer 11, Kahn Negative, Hinton Negative **Kline N gative** by fourth laboratory (syphilis clinic-controlled).
N Clinical Evidence of Syphilis acquired or prenatal Mother has had miscarriages.
N Exposure in many years.
12/28 to 12/29 **Treatment Continued.** Fever slowly subsides Occasional evening chills
Murmur unchanged.
Kolmer Kahn, Hinton, and Kline tests continuously and completely negative.

Discussion

1 A classical series of serological conflicts, probably on nonspecific basis in patient who probably had transient febrile, possibly septicemic condition ith recovery
2. Treatment for syphilis was carried through because it was impossible to decide absolutely whether the patient had had syphilis or not.

Fig. 37

THE CHECKING OF A POSITIVE SEROLOGIC TEST REPORT*

1. Condition of mailing, receipt, elapsed time, hemolysis, stoppers, etc.
2. Who performed the test?
3. What procedures used? Standard
4. How strongly positive? Can a titer be obtained
5. When was the test performed in relation to the biologic background of the person: menstruation, intoxications, fever, intercurrent acute infection, other chronic infections, subacute bacterial endocarditis, anesthesia, alcoholism?
6. Any malaria, lepra, yaws, tuberculosis, bacteremia. Review Fig. 83.
7. Result on repetition
   a. By same laboratory on original specimen if still available and on fresh specimen
   b. By an approved check laboratory (United States Public Health Service standard)
   In series or after an arsenical or bismuth provocative effect (suspected of nonspecificity)
8. Result of a physical examination of the patient.
9. Result of the epidemiologic (contacts and family) inquiry. Go as far as you can.
10. The history of infection (30 per cent to 60 per cent margin of error and almost worthless in women)
11. The spinal fluid examination—if case weighs "50–50" or in opinion of an experienced referee or consultant.
12. Observation—invariably if case weighs "50–50," often even if not (six months to yearly)
13. "No case intuition—a factor in expert decision
14. Treatment on suspicion. Response of symptoms may be nonspecific of tests, unreliable. Do not treat genital lesions on suspicion, merely to observe response. "On suspicion" really should usually amount to the same thing as treatment appropriate to positive diagnosis.

Moore and his associates* have suggested the following procedures when biologic false positive serologic tests for syphilis are suspected: Careful history; careful physical examination for evidences of acute infection preceding the questionable serologic test, with special reference to lymph nodes, spleen and lungs; search of blood smears for malarial parasites; blood smears for infectious mononucleosis; blood test for heterophile antibody (the Paul-Bunnell test) which is specific for infectious mononucleosis; determination of the sedimentation rate; repetition of the serologic test for syphilis by several different technics and in several different laboratories; performance of a verification test; testing the patient's serum by complement fixation with spirochetal antigen; testing the patient's serum with wholly nonspecific antigens such as those prepared from bacteria; prolonged serologic follow-up; examination of the members of the family and sexual contacts; examination of the cerebrospinal fluid, if decision cannot be reached earlier. These authors consider the provocative procedure worthless. They advise withholding antisyphilitic treatment unless and until the diagnosis of syphilis is proved.

* Stokes, J. H. Amer. J. Syph. Gonor. and Ven. Dis. 23:349, 1939. Moore, J. E., Eagle, H. B. and Mohr, C. F. J.A.M.A. 115:1602, 1940.

The highest positive efficiency of the blood serological tests is reached in the period extending from about three weeks after the appearance of the chancre to the height of secondary manifestations, covering roughly about six months. From this pinnacle of efficiency the proportion of positive serological results obtained from the blood gradually declines.

The percentages expressing this decline in efficiency vary substantially with different writers and are a function of three factors, the last of which is too often forgotten. The first factor is the delicacy of the test, as performed in the laboratory; the second is the treatment which the patient has received, and the third is the amount of clinical skill and judgment applied in the clinical examination in conjunction with the test to recognize those cases which fail to yield positive

serological results. Many of the high proportions of positive serological tests reported in latent recurrent and late syphilis are the result of serological rather than combined serological and clinical diagnoses in which the positive test itself rather than the clinical manifestations of the disease, constitutes the proof of the presence of syphilis. The proportion of initially blood serologically negative syphilis can be considerably increased and the positive group correspondingly diminished by the use of multiple clinical procedures for identifying the disease without the aid of positive blood test and by the systematic employment of the Wassermann series. The provocative procedure is unreliable Certainly it is out of the question to accept as conclusive opinions hich are based largely on the serological material sent to laboratories with the presumption of syphilis raised by the less critical judgment of general medical men. Inasmuch as it sometimes takes a pretty obvious and hence probably serologically positive syphilis to arouse suspicion, such results may read high in the proportion of positive t negative.

As examples of the extremes in estimation hich are current, Craig summary in latent syphilis quotes Grosser as obtaining 83.3 per cent positives by complement fixation technic, while Vedder gives 80.7 per cent. Craig own results yield 68.1 per cent. Fordyce, in 881 late cases, obtained 72.3 per cent positive reactions on the blood The results obtained with complement fixation procedure in the Mayo Clinic on 252 cases of untreated syphilis summarized b Des Brisay are given in Fig. 38

Fig. 38.

PERCENTAGE OF POSITIVE BLOOD WASSERMANN REACTIONS IN TYPES OF UNTREATED SYPHILIS (252 CASES)

	Cases.	Positive.	Per cent.
Visceral	18	18	100 0
Latent	49	46	93 8
Cardiovascular	20	17	85 0
Osseous	19	16	84 2
Cutaneous	22	18	81 2
Mucous membrane	10	8	80 0
Neurosyphilis	114	47	41 2

Des Brisay Mayo Clinic

These figures, while obtained largely from one of the older serological technics, illustrate very clearly the difficulty of estimating the frequency of positive reactions in an aggregate including all types of syphilis Neurosyphilis stands out in this series in a way which suggests almost an inherent trend toward serological negativity on the blood On the other hand it must be remembered that neurosyphilis is the symptomatic syphilis of internal medicine and that diagnosis can frequently be made by signs quite irrespective of serological findings. On the other hand, in visceral syphilis, where the disease is almost never even suspected unless the routine serological tests indicate its presence it is to be presumed that 100 per cent of positive serological tests will be obtained Cardiovascular syphilis often quite as important as neurosyphilis as a source of diagnostic error associated with negative blood serological tests, stands comparatively high in the list of positive Wassermanns because it is so largely diagnosed by the blood findings rather than the clinical examination

Using the older serological technics, Stokes and Brehmer found, in 200 railroad men and farmers, as they entered the Mayo Clinic, an incidence of positive blood Wassermann reaction of 42 to 50 per cent. In 200 syphilitic patients hose chief complaint was "stomach trouble, large proportion of whom had neurosyphilis, Brown and Stokes found 43.5 per cent positive blood Wassermann reactions. Des Brisay succeeded in demonstrating, in his series of cases, the spontaneous decline of the proportion of posit ve serological tests through the years of duration of the ordinary syphilitic infection, beginning with the positive blood and spinal fluid

through the negative blood and positive fluid and finally to complete serological negativity with lapse of time

The more distinctly modern figures based upon the Kolmer modification of the Wassermann test, are given in Fig. 39 The same considerations, of course apply to some extent to a table of this sort, with reference to the relative weight of clinical and serological diagnosis but certainly these figures satisfactorily indicate the serological expectancy of a positive test as performed today in one of the best laboratories of the world Again however in cardiovascular and neurosyphilis we believe that the proportion of seronegative cases would be higher if clinical diagnosis could be stepped up to its maximum efficiency In general the more acute the clinical judgment exercised and the more the collateral means for proving syphilis are used the lower will be the percentage of positive blood serological reactions in the syphilis which is diagnosed.

Fig 39

INCIDENCE OF POSITIVE KOLMER WASSERMANN REACTIONS IN VARIOUS TYPES OF SYPHILIS

Type of syphilitic involvement.	Blood Wassermann positive, per cent.	Spinal fluid Wassermann positive per cent.
Primary 5–14 days	41	
10–14 days	73	
3– 4 weeks	84	
4– 6 weeks	91	
Secondary	99–100	
Latent (men)	90	
(women and children)	50– 80	
Chronic skin and mucous membranes	90– 95	
Bones and joints	80– 95	
Gastric	80– 85	
Liver and spleen	90– 93	
Cardiovascular	80– 98	
Ear nose and throat	70–100	
Iritis	100	
Prenatal latent	40	20– 40
Prenatal skeletal	70	
Interstitial keratitis, iritis, choroiditis, etc	90– 93	
Neurosyphilis, asymptomatic, (early)	83–100 (in early [illegible])	20– 40
Asymptomatic (late)	70– 90	80– 90
Tabes dorsalis	70– 85	96
Primary optic atrophy	83	93
Paresis	98–100	100
Cerebrospinal	80– 90	93–100

A tabular summary of the sensitivity of current serologic tests based on the "early-late" type of chronology much used in public health work is given in *Fig. 40*

The Effect of Treatment on Serological Reactions.—Treatment for syphilis has the general effect of reducing serological tests from positive to negative The degree to which such an effect is obtained is, of course dependent on a number of factors, including the amount and kind of treatment, the character of the infection, its duration and so forth. It is a comparatively easy matter to reverse serological reactions in the first few weeks of the infection It

Fig. 40.

SENSITIVITY OF VARIOUS SEROLOGIC TESTS IN TREATED AND UNTREATED CASES OF SYPHILIS*

Name of test.	Early untreated primary and secondary (45 cases)	Less than 4 years receiving varying amounts treatment (119 cases)	Over 4 years, treated and untreated (approx. 218 cases)
	Complement Fixation

Fig 41.

SEROLOGIC RELAPSE AND BLOOD SEROLOGY IRREVERSIBLE (WASSERMANN FASTNESS) OBTAINED IN THE COOPERATING CLINICS, BY DIAGNOSIS ON ADMISSION

Diagnosis of early syphilis.	Serologic relapse, per cent.	Blood serology irreversible (Wassermann fast). 1 Year per cent.	Over 1 Year per cent.
Seronegative primary	6 4	1 2	2 6
Seropositive primary	9 9	7 5	7 0
Secondary (first year)	10 7	5 5	7 8
Secondary (Delayed)	10 8	7 7	13 6

Adapted from Table 14 Cooperative Clinical Studies in the Treatment of Syphilis, Ven Dis. Inf., 1932.

becomes exceedingly difficult where the disease had been literally bred into the bones and tissues of the patient, as in prenatal or congenital syphilis. Moore and Kemp after Keidel and Moore had paved the way by years of routine weekly serological tests on all patients under treatment for syphilis were able to show very beautifully the gradient of serological decline from positive to negative in early syphilis and its relation to the type of treatment administered. While this will be more fully discussed later their composite figure is reproduced here to show the average rate of decline of the Wassermann reaction from strongly positive to weakly positive and finally to negative under treatment, and the tendency of the curve to become positive even though originally negative when treatment is allowed to lapse (*i. e.*, is intermittent instead of continuous) Fig 41 illustrates in terms of serologic relapse and irreversibility the principle that so far as treatment effect on blood serology is concerned, seropositive primary syphilis should be classified with secondary rather than as primary syphilis.

The behavior of the serological reaction under treatment is by no means always according to schedule. In the later phases of the disease as well as in asymptomatic latency reversals to negative may be accomplished with almost unbelievable ease and again, *pari passu*, the seemingly most eligible case, ideally handled, may obstinately refuse to show serological response. Patients may undergo an easy and early reversal to negative only subsequently to become positive again during a rest interval or lapse thereafter to remain irreversibly positive indefinitely On the other hand a serological reaction may be only weakly positive at the outset, to become strongly so after treatment is initiated, to remain strongly positive throughout the entire course of treatment, even over a period of years and then, without explanation, to become promptly or slowly negative and to remain so after treatment has ceased. There is often a definite lag between the administration of treatment and the securing of serological effect. This is seen in nonspecific therapeutic methods, such as fever therapy in which there is no necessary parallelism between clinical improvement and serological response, though satisfactory serological response may be secured months or even years after the administration of the critical treatment in the case Reference has already been made to the spontaneous gradient of decline demonstrated by Des Brisay in our serological results in untreated syphilis Beerman (1939–42) summarized his own and other observations on the retarding, "lag" effect of bismuth on blood serologic reversal when used in simultaneous combined treatment in early syphilis, with the arsphenamines and mapharsen.

Serological response varies not only with the treatment and characteristics of the individual case, but with the method of measurement, or testing employed. Thus it may be legitimately urged with respect to a given serological procedure that its delicacy is appropriate to treatment while inappropriate to general diagnosis In other words, it has a distinct tendency to give false positives which are less serious when obtained in a treated case because they merely result in a perhaps harmless or even desirable prolongation of treatment, while they are extremely undesirable in undiagnosed patients on account of the risk of fastening a diagnosis of syphilis upon a person who does not have the disease.

The Fixed Positive Blood Serological Reaction (Sero-resistance, Reaginfastness).—Serological reactions for syphilis which will not become negative under treatment are spoken of as fixed, irreversible or resistant *positive*

Fig. 48.

CURRENT USES FOR AND VIEWS ON QUANTITATIVE BLOOD SEROLOGIC TESTS

1 Still relatively esoteric procedure not easily available without exceptionally high grade f usually noncentralized laboratory service (so far available routinely in only one stat) The so-called "Vernes syphilimetry widely used in pre-W France an early example
2. Of littl value in diagnosis as yet except in congenital syphilis.
3. Of most significance in treatment best studied nd most useful in early syphilis, and in the kild of a syphilitic mother
4 Usually conducted as reagin titer estimation. For comparable results all test must be run in the same laboratory (Moore and Eagle 1941)
5. When thus empl yed, it ppears that
   Wide variations in reagin titer ppear (0 t 1600 units) Titer tend t ru t higher levels in early than in lat syphilis.
   b These variations appear even in infections hich are otherwise linically similar in manifestations and intensity
   Titer is however generally lower in primary tha m secondary syphilis
   d It is initially lower and falls more rapidly under treatment in clinically mild (few isolated lesions) secondary syphilis than in florid" extensive secondary syphili (Crosby nd Campbell, 1941)
   In early syphilis (Moore and Eagle series) the primary syphilis mean as 104.3 plus-minus, 13 74 units, media 43.2 plus-minus 17 92 units; the secondary syphilis mea w 179.6 plus minus, 7.54 units; median 142.5 plus minus 9 45 units.
   f In late syphilis (same uthors) there are no correlations bet een the type or gravity of the involvement and the serologic titer The range is from 0 t 1600 units, the mean titers of the five groups or types of involvement ranging from 21 5 t 44 1 units. Late latent and tabetic neurosyphilis tend t have lower titers.
   g Reagin titer though educed by treatment in late syphilis not guide to the lessening of gravity of the infection or t clinical improvement under treatment.
   h. Reagin titer does not increase in proportion t the duration or completeness of the latency It is not direct expression of the degree of immunity or resistance t infection.
6. Used as measure of effectiveness, reagin titer indicated that five arsenicals commonly used in treatment of early syphilis did not differ materially in their bility t lower the titer Moore and coworkers (1936) concluded this was insufficient evidence to prove equal all round effectiveness.
7 A sudden rise in reagin titer may presage relapse in early syphilis (Kahn, 1930).
8. A rise in titer in the blood of the child of syphilitic mother in serial examinations post partum indicates the presence of the infection (not merely carry-over from the mother blood)
9 Working with fever alone and with combined fever and hemotherapy Simpson, Rose and Kendell (1942) showed (Kahn quantitative procedure) that
   a. Th lower th initial titer in early syphilis, the more rapid the reversal t negative
   b A provocative effect is observed at the institution of treatment in some cases (observed but discounted by Crosby and Campbell, 1941 in seronegative primary syphilis) Possible lag effect.
   In primary syphilis treated twice weekly serologic reversal required from twenty three t sixty-four day depending in part on the titer at the outset in secondary syphilis treated once weekly fifty to ninety-three days; in secondary syphilis treated twice eekly in twenty-eight t sixty-six days. The uthors conclude however that semiweekly treatment has no advantages over weekly treatment the rat of reduction being dependent on the original titer
   d. The results of single f ver-chemotherapy session in primary syphilis ere essentially the same as for multiple sessions.
10. In patients with persistent seropositiv reactions or delayed reversals, under treatment, reagin titer methods may show favorable progress (decline) or unfavorable progress (increase) hen ordinary test indicat simply persistent positive reaction (Kahn, Simpson, et al)

Fig 42.—Continued.

11 Ninety-nine per cent of th bserved extreme titer rang (1 t 5400 units) falls in the classification of "strong positive or 4 plus" by ordinary nonquantitative procedure
12. The original dictum of Wile and Hasley deserves remembering—the more sensitive the procedure (i.e. detection of minut amount of reagin) the farther i the serologic "cure of syphilis removed; and it may be added, illustrated by Crosby nd Campbell, the less serongative primary syphilis there is.
13. Quantitative procedure is of great importance in prognostic and therapeutic study of the spinal fluid (see prognostic types) and Kahn (1939) emphasizes reagin content of spinal fluid control of treatment effect.

reactions. Again the interpretation of the phenomenon must vary with the amount of treatment, the character of the disease in the patient and the methods of testing employed.

In all probability w shall never fully understand the significance of the irreversible positive until the source of the Wassermann antibody is definitely known. If it comes from minute obscure focus of spirochetes, perhaps in an insignificant location, the reagin being the product of the breakdown of the organisms, the interpretation of the fixed-positive patient situation must

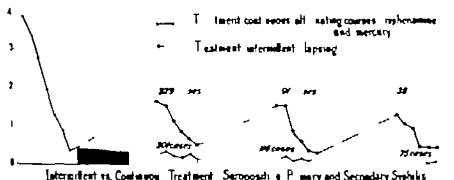

Fig. 43.—The Wassermann "gradient of reversal from strong positive (4) t negative (0) in early syphilis under treatment. The upper line (succession of peaks) represents the relapses t positive under intermittent treatment in contrast with the steady fall to negative under continuous treatment. (From Moore nd Kemp, Bull. Johns Hopkins Hosp Vol. 39 1926 Published by Williams and Wilkins Co.)

be somewhat different from that which ould prevail if the irreversible positive could be regarded as permanent metabolic change in those previously infected with syphilis but perhaps no longer harboring the organisms. In the former the positive test means active defense, organisms in process of destruction. In the latter case one could think of the positive serological test as species of scar which could be regarded as of no importance. The possible interpretation of the Wassermann reagin as an agent in the defense mechanism ould make the retention of positive Wassermann almost theoretical desideratum in certain cases.

There is not a little evidence to suggest that a positive serological reaction is by no means necessarily disadvantageous *ipso facto* Some of the gravest forms of syphilis carry the patient on to dissolution with absolute and continuous serological negativity while some of the most harmless and most protracted latencies seem to be accompanied by absolutely irreversible positive blood serological reactions (the miliary type of focal defense à la Warthin)

Definition of a Fixed Positive Reaction.—While it is impossible to define precisely what a fixed positive blood serological reaction is, one may say roughly for purposes of discussion, that it is a blood serological reaction which remains positive after twenty or more intravenous injections of an arsphenamine given in combination with twenty weeks of intramuscular heavy metal therapy with either bismuth or mercury or both. Serological tests may be regarded as persistently positive under these circumstances, even though there may have been a brief interval in which the intensity of the positive phase was apparently reduced or rendered fluctuating by the treatment. Even though such cases are reduced to negativity by prolonged *and intensive treatment, they tend to become positive again* at once upon the cessation of treatment and at times even to gain in positive intensity from a comparatively mild positive at the start to a strong positive at the close of treatment. The first concern, in the interpretation of pictures such as this, is the possibility of an underlying cardiovascular or neurosyphilitic complication unrecognized in the ordinary management of the case. A fixed positive blood serological reaction automatically raises the question as to whether the spinal fluid has been examined. If this has not been done, it *must* be done before any real interpretation of the findings or the proper course to pursue can be made. Similarly the presence of a resistant positive blood serologic reaction in a patient under treatment always demands a painstaking physical examination of the cardiovascular mechanism. Unfortunately the signs of cardiovascular change in such cases may be equivocal or wanting. It is then only possible to tell the patient that repeated examination over a period of years is absolutely necessary to the interpretation of the situation. In our more recent observations, it has seemed that the blood serological reaction in an obscure and gradually developing subthreshold cardiovascular syphilis tends toward frequent periods of transient negativity, fluctuations in positive strength and ultimately to a complete negativity some time after treatment is discontinued while the cardiovascular lesion continues its slow progress. This is perhaps particularly true of the early case and less in the later fully developed case in which definite physical signs can be recognized.

In some cases a liver slightly enlarged, a palpable spleen, obvious general enlargement of the lymph nodes, may provide a suspicion as to the reservoir of infection which is maintaining the serological positive. On the other hand, all signs or suggestions as to a physical site may be absent and the disease may present itself to both patient and physician merely as a positive serological test. It can never be overemphasized that the prolonged and intensive treatment of a patient whose only evidence of the disease after most painstaking examination, is a positive serological test on the blood, is a matter requiring the most discriminating judgment and painstaking consideration and that it is at the present day more over than underdone. This question is more fully discussed and the guiding principles to be used are presented in the discussion of treatment in latency.

The Too-Readily Reversible Positive Serological Reaction.—Moore and Kemp (1926) succeeded in showing that in early syphilis at least, those patients who fail of a sufficiently prolonged or at least a typical degree of serological resistance and who become serologically negative in a very short time have apparently a distinctly more marked tendency toward relapse. This easy reversal of the blood serological reaction accordingly becomes a trap for the unwary physician in the early treatment of the disease and a means by which

infectiousness is perpetuated through the too-early discontinuance of treatment and through ill-advised assurances to the patient regarding his supposed noninfectious condition while serologically negative It may be considered a rule of thumb that the patient under standard treatment with an arsphenamine and a heavy metal whose serological reaction reverses to negative before

Fig 44.

PROCEDURE FOR THE PHYSICIAN DESIRING INTERPRETATION BY MAIL OF BLOOD SEROLOGIC REACTIONS*

He should supply the following information for questions on serologic test involving patient or patient-type

1 Age sex, marital and family status of patient.
2. Contact and exposure data.
3. Adequate clinical examinations reported in detail, conforming approximately to the schedule i Chapter 11
4. Who did the serologic test?
5. What methods were employed, and what checks?
6 Result of repetition and by whom performed.
7 With reference t intercurrent factors relating t false positives including:
   a. Residence in tropics and so forth (malaria, lepra, y)
   b. Intercurrent infectious disease especially tuberculosis and streptococcal infections.
   Fever of any kind.
   d Relation of test t pregnancy menstruation, and delivery
8. Previous treatment for syphilis and effect on tests.
9 A satisfactory report on a completely and properly performed spinal fluid examination.
10. Results of investigation of the family

On serologically fast cases the following special information is essential

1 Time in the infection that treatment was begun.
2. Total number of arsenical and heavy met l treatment received.
3. Information on dosage employed.
4. Over how long total period was treatment spread
5. A schedule indicating the grade of irregularity if any
6. Time in the course of treatment that most irregularity appears.
7 Report of an adequat spinal fluid examination.
8. Physical status of the case both as of the present, nd if possible, at the time infection was acquired.

The doctor get poor nswer because he gives no history of the case in serologic fast questions (81 per cent); gives no clinical data (40 per cent); provides no spinal fluid examination report (81 per cent). Avoid short-cut tests.

Comment

1 Do not ask questions about serologic-fast case ithout providing or arranging for a complete and accurat spinal fluid report.
2. Scrutinize the false positive as closely as the negative including biologic as well technical possibilities of error
3. Laboratories creat confusion by reporting eak positives t any but experts.
4 Much trouble with serologic results under treatment comes from rest periods, lapses, irregularity in early treatment

* From "8,000 Questions the Doctor Asks About Syphilis"—Stokes, Ingraham and Stannard Ven. Dis. Inform 21 147 1940.

the eighth week of his treatment, is showing a positively dangerous degree of serological response and one which predicates a distinct tendency to relapse or to continuance of the syphilitic process under the cloak of a negative serology A reversal to negative in an early case nearer the sixteenth than the eighth week, provided the negative persists, is of favorable rather than unfavorable significance for the ultimate outcome

Definition of a Fixed Positive Reaction.—While it is impossible to define precisely what a fixed positive blood serological reaction is, one may say roughly for purposes of discussion, that it is a blood serological reaction which remains positive after twenty or more intravenous injections of an arsphenamine given in combination with twenty weeks of intramuscular heavy metal therapy with either bismuth or mercury or both. Serological tests may be regarded as persistently positive under these circumstances, even though there may have been a brief interval in which the intensity of the positive phase was apparently reduced or rendered fluctuating by the treatment. Even though such cases are reduced to negativity by prolonged and intensive treatment, they tend to become positive again at once upon the cessation of treatment and at times even to gain in positive intensity from a comparatively mild positive at the start to a strong positive at the close of treatment. The first concern, in the interpretation of pictures such as this, is the possibility of an underlying cardiovascular or neurosyphilitic complication unrecognized in the ordinary management of the case. A fixed positive blood serological reaction automatically raises the question as to whether the spinal fluid has been examined. If this has not been done it *must* be done before any real interpretation of the findings or the proper course to pursue can be made. Similarly the presence of a resistant positive blood serologic reaction in a patient under treatment always demands a painstaking physical examination of the cardiovascular mechanism. Unfortunately the signs of cardiovascular change in such cases may be equivocal or wanting. It is then only possible to tell the patient that repeated examination over a period of years is absolutely necessary to the interpretation of the situation. In our more recent observations, it has seemed that the blood serological reaction in an obscure and gradually developing subthreshold cardiovascular syphilis tends toward frequent periods of transient negativity, fluctuations in positive strength and ultimately to a complete negativity some time after treatment is discontinued, while the cardiovascular lesion continues its slow progress. This is perhaps particularly true of the early case and less in the later fully developed case in which definite physical signs can be recognized.

In some cases a liver slightly enlarged, a palpable spleen, obvious general enlargement of the lymph nodes, may provide a suspicion as to the reservoir of infection which is maintaining the serological positive. On the other hand, all signs or suggestions as to a physical site may be absent and the disease may present itself to both patient and physician merely as a positive serological test. It can never be overemphasized that the prolonged and intensive treatment of a patient whose only evidence of the disease, after most painstaking examination, is a positive serological test on the blood is a matter requiring the most discriminating judgment and painstaking consideration and that it is at the present day more over- than underdone. This question is more fully discussed and the guiding principles to be used are presented in the discussion of treatment in latency.

The Too-Readily Reversible Positive Serological Reaction.—Moore and Kemp (1926) succeeded in showing that in early syphilis at least, those patients who fail of a sufficiently prolonged or at least a typical degree of serological resistance and who become serologically negative in a very short time have apparently a distinctly more marked tendency toward relapse. This easy reversal of the blood serological reaction accordingly becomes a trap for the unwary physician in the early treatment of the disease and a means by which

test. Greenbaum, in an interesting study of 100 cases, was able to compile 50 examples of diagnosed syphilis which gave positive Kahn tests and negative Wassermann tests, and a like number which gave positive Wassermann tests and negative Kahn tests. Houghton *et al.*, however reported 76 positive Kahn reactions when the Wassermann was negative out of 40 cases, against 21 positive Wassermann reactions with negative Kahn tests out of 16 cases, all the patients having undoubted syphilis. Walker in 181 cases of diagnosed syphilis, reported all Kahn reactions positive while only 107 gave positive Wassermann reactions, 43 moderately positive reactions and 26 negative. Berry Ey and De Long in 363 cases in the various stages of syphilis, found that 256 gave positive Kahn reactions and negative Wassermann reactions while only 27 gave positive Wassermann and negative Kahn reactions.

The more recent advocacy of multiple tests of differing types is well presented by Boerner Lukens and Gilman (1938) who found three tests yielding the highest proportion of positives; and Schoch (1939) who recommends five tests under clinic control.

It would appear therefore, that the examination of the blood of a seronegative patient by a precipitation reaction, especially if some of the older Wassermann technics have been used to obtain the original negative is an essential part of the interpretation of the negative serological reaction.

Where a particular type of syphilis is suspected in the patient, but the serological result is negative it cannot be said at the present time that any one test procedure should be invoked for reinterpretation. The results of various observers are too conflicting and the advantage of any particular test too small to permit of any other generalization than that two or more test methods, including a complement fixation and a precipitation technic, should be employed

Danger of "Stepping Up" Sensitiveness of Tests.—Every attempt to reinterpret the negative by stepping up the sensitiveness of the procedure used, is fraught with a very definite element of danger from nonspecific effect. This applies, for example as Kolmer points out, to the reading of the Kahn test after refrigeration instead of at the completion of the reaction as required by the standard procedure. From such intensification including the use of highly cholesterinized antigen, serious trouble is sure to ensue except, perhaps, in the interpretation of known syphilis under treatment. The proper place for the sensitive procedure in eliminating false negatives is at the beginning of a study of any patient's serum rather than at the end. It is more important, in the main to eliminate false positives than false negatives.

Serial Testing and the Provocative Procedure.—As in the case of a suspected false positive, the suspected false negative may be tested by serial repetition, the number varying with the circumstances of the case

While the original provocative which consisted of a series of daily serologic tests following a single injection of an arsphenamine, has lost much of its significance through the study of nonspecific reaction previously referred to, there still remains a residue of usefulness in the procedure which should not be wholly discarded. Most of this residue resides in the worth of a series of tests as distinguished from a single test. On the other hand there is sufficient accumulated evidence from Gennerich in 1910 to current experience, to indicate that a rise in reagin titer both in the blood and spinal fluid does follow the use of antisyphilitic treatment in syphilitic persons, and that this may have some confirmative value in the more complex groups of procedures required for diagnosis in doubtful cases. The decreasing use of the provocative is due partly to fear of therapeutic shock effect of stirring up the disease, if it is present, without continuing treatment to the practical difficulties of daily blood-tests and the expense of their performance to the now well

recognized fluctuation in the daily serologic results even of the best laboratories and to the nonspecific possibilities mentioned Probably the most useful form of provocative procedure in our experience at least is the repeated injection of a bismuth compound at weekly intervals for four or five injections with serologic tests performed simultaneously with each injection. Such heightened positiveness as appears occasionally assists materially in confirming the belief that a patient who would ordinarily fall in the category of doubtful is actually the victim of a syphilitic infection By such a method there is little or no danger of therapeutic shock, and if the result is well defined its confirmatory value is often gratifying Quantitative procedure can be invoked in this method and a titer below four units of reagin may justifiably be regarded at the height of the test as uninterpretable.

Fig 45

CERTAIN POSSIBLE COMBINATIONS WITH THE NEGATIVE BLOOD SEROLOGIC REACTION

A negative blood serologic reaction may occur with

1 A positive darkfield, both early and late.
2. Secondary syphilis, especially treatment resistant
3. An active cutaneous late syphilid
4. An active bone lesion, especially of the palate and clavicle
5. *Spirochaeta pallida* in the blood.
6 A positive spinal fluid.
7 *Negative provocatives and positive* spinal fluid.
8. Early cardiovascular syphilis.
9 A negative spinal fluid, and positive neurological signs of syphilis, arrested tabes, gastric crises, Charcot joints, vascular syphilis of the brain.
10 Following positive serologic reaction and the reverse
11 Stigmata of congenital syphilis, including active interstitial keratitis.
12. Positive spinal fluid and negative neurological examination
13. Negative provocative negative spinal fluid and neurological examination, and positive eye signs of syphilis (peripheral chorioretinitis, congenital child with stigmata)
14 Negative spinal fluid, negative neurological examination, no stigmata of congenital syphilis, eighth nerve deafness, positive Bárány positive therapeutic test. (The infection in this case must be identified by examination of the family
15. A history of genital lesion, an eighth nerve deafness, anomalous genital signs, slight pleocytosis in the spinal fluid, paraesthesias and positive therapeutic test.
16. Negative clinical examination. Positive history and later positive findings on follow-up
17 Negative history and clinical examination. Returns later with positive cardiovascular signs.

Serological Tests and the Determination of Infectiousness.—The following statement, destined to be repeated in a subsequent chapter is placed here to catch the eye of the reader perusing this material merely for information on the serological tests. There are few misconceptions of which it is more difficult to disabuse the practitioner than the feeling that the serological tests for syphilis determine the infectiousness or noninfectiousness of a given case Once assured that his blood test is negative the patient takes it naïvely for granted that his liberty is restored and that he can once more from the standpoint of transmission of the disease *comport himself a a well man. Too often the* physician, acting under the same misconception encourages the patient in this delusion The facts of the matter are these **Infectiousness in syphilis is never determined nor is noninfectiousness proved by the outcome of any**

serological test, single or repeated. Noninfectiousness in syphilis is the result of lapse of time and absence of infectious lesions. While the serological tests tend to become negative with both time and treatment, and tend to be positive when infectious lesions are present, there is no necessary correspondence between the two. The exceptions to the rule are too often the most tragic that can be imagined. The wise physician will therefore allow no relaxation of any precautions he may have ordered against the transmission of the disease on the basis of the reversal of a blood test to negative or even of its persistence as negative over a considerable period. He will depend instead upon his knowledge of the age of the infection, the peculiarities of the individual case (for there is a definite infectious relapsing type), and on the results of prolonged systematic empirical treatment with the arsphenamines and the heavy

Fig. 40

THE CLINICAL CONTROL OF SEROLOGICAL TESTS

1. Accept no serological test as an infallible diagnosis or absolute exclusion, without clinical examination.
2. Accept no positive test without at least one repetition.
3. Know the conditions known or suspected to give biological false positives.
4. Insist that your laboratory run a complement fixation (Wassermann) and a precipitation test parallel on all specimens, and report both.
5. Insist on one semiquantitative report, especially in treatment and on spinal fluid.
6. Repeat all doubtful or indeterminate tests.
7. Repeat all negatives at least once if clinical suspicion warrants.
8. Avoid checking different laboratories against each other on the same specimen. Use only a laboratory which you know does this periodically en bloc. Individual practitioners' attempts at this sort of control rarely do more than confuse.
9. Laboratories working without clinical control, or refusing it, are apt to be inaccurate.
10. Serial repetition of a test with initial negative results with or without an arsphenamine injection (provocative) adds about 18 per cent to the possibility of obtaining an authentic positive.
11. A weekly test after treatment begins or is resumed, following a negative may during a month disclose a positive returning to negative (therapeutic provocative).
12. In seronegative primary syphilis one or two such tests are essential.
13. Provocative effects in the spinal fluid may be observed but are delayed.
14. Expect conflicting results in late syphilis; but question a laboratory which gets negatives or weak positives in acute secondary syphilis or untreated early paresis.
15. Distrust frequent reports of "clears slowly" and "anticomplementary" as reflecting on the laboratory as well as the specimen.

metals and on frequently repeated physical examinations with special reference to the regions in which infectious lesions are known to appear (see Chapter XIII). In particular he will never authorize the relaxation of precautions against the transmission of the disease in sexual intercourse merely on the strength of single or repeated negative serological tests.

The Two Types Used Simultaneously Are Essential.—The evidence for the ability of complement fixation to detect a proportion of undoubted positives not recognizable by precipitation and *vice versa* is too strong to be denied. Moreover, and this point, we believe, has been too easily overlooked by organizations which have given up complement fixation tests in favor of precipitation procedure, there is a vast body of knowledge accumulated around the positive and the negative Wassermann reaction which cannot be transferred except in the course of a rather long interpretative interlude, from the comple-

ment fixation to the precipitation test. This body of clinical knowledge is a priceless accumulation, the only code to which decision in the doubtful case can be referred. It may therefore be accepted as the sound opinion of the present day that no laboratory is performing its final duty toward the diagnosis of syphilis or serving its patrons properly which is not reporting the results of a complement fixation and a precipitation test simultaneously performed on every serum Screen tests are only preliminary

The Routine Blood Serological Test.—The first edition of this book was inclined to oppose the attempt to routinize serological tests for syphilis as part of every medical examination feeling the justice of the objection on the score of expense and dreading further substitution of a mechanical procedure for an alert, receptive highly suspicious frame of mind Inevitably however the trend is away from this first position Simplification is doing away with objections on the score of expense the perfection of the balance between specificity and sensitivity with striking increase in both, is giving to the modern serodiagnostic test a reliability much superior to the older Wassermann procedure. Whole fields of syphilis, particularly the osseous and the visceral, will inevitably be dependent to some extent on serological diagnosis for the initial clue if not the final confirmation. Wherever surgery touches syphilis to its notable discomfiture in the past, protection of patient from misdiagnosis and of surgeon from risk of infection, begins with the application of routine serological tests The disappearance of syphilis below the threshold of visibility under modern methods of treatment leaves large numbers of patients whose condition can be appraised or identified only by the habitual use of serological tests. The newer conception of the asymptomatic carrier discussed in the earlier chapters requires for evaluation and for the protection of individual and public health the absolute routinization of the blood test for syphilis. Mass serologic testing for the determination of the presence and prevalence of syphilis in population groups ("the Wassermann barbeque") has become established practice in public health and military medicine It is no longer justifiable to limit the recommendations for such testing to the age period of seventeen to twenty-five, for it becomes almost equally simple and inexpensive to apply to all medical examinations from the moment of conception to the hour of death But is the routine test sufficient? Not at all Inevitably it will become a crutch and not a clue the moment it is divorced from or substituted for the painstaking physical examination of the patient Just as all appraisal of the diagnostic worth of serological tests must end in the clinic as a court of last resort, so physical examination maintains the one and most essential check upon the blood diagnosis of the disease. It is precisely in the fields of cardiovascular and neurosyphilis, the most critical aspects of the syphilology of the future as it concerns the individual patient, that serological tests still have their highest margin of error

THE SPINAL FLUID EXAMINATION IN THE DIAGNOSIS OF SYPHILIS

The Clinical Importance of Spinal Fluid Examination.—Too often looked on merely *as a fad and the pet of specialists the spinal fluid examination has* fundamental importance in the detection of syphilis *per se* in the complete examination of the syphilitic patient once his infection is recognized by other means as an indispensable guide to treatment, and as a test for "cure" or arrest.

The earliest application of the spinal fluid examination to the detection of syphilitic involvement of the cerebrospinal axis was that of Ravaut, in 1903, and of Widal and Sicard which antedated the first performance of the Wassermann test on the fluid by Levaditi and Marie in 1906. One of the most important steps in the rapid popularization of the spinal fluid examination was the demonstration that syphilitic involvement of the nervous system occurred, not late in the disease but early and that the application of the spinal test in the primary secondary and latent period would often reveal st t of ffairs of great importance t the patient future, though not betrayed by any symptoms whatever By 1918 it as conclusively show that early neurosyphilis could be recognized by spinal fluid examination before the ppearance of secondary lesions.

Abnormalities of the spinal fluid often of the most pronounced type precede by months or even years the first signs that can be elicited by neurological examination, and the first appearance of symptoms of a subjective type. It has become apparent that there is no necessary correlation between symptoms and spinal fluid changes so that a person with every serological evidence of severe neurosyphilis may have no symptoms or other neurological findings, while one with severe symptoms may have a normal fluid The fact *that the spinal fluid in itself* may be the sole guide to an otherwise asymptomatic and obscure involvement of the most important group of structures affected by the disease, has justified the insistent demand of syphilologists that the test shall not be an optional part of the management of early and latent syphilis, but shall be an absolutely routine requirement for all ca es at the proper time during their course. As a guide to the effect of and need for treatment in both early and late neurosyphilis, the examination of the spinal fluid has become indispensable, and failure to insist on the test may rank as culpable negligence. Should the patient refuse it his blood is at least on his own head.

General Considerations.—The earlier in the course of a syphilitic infection the spinal fluid examination is done, the higher is the proportion of abnormal findings. Abnormal fluids are found in the primary stage in from 7 to 25 per cent of the cases. In the fully developed secondary stage untreated various reports range from 26 to 78 per cent, with a probable mean of about 40 to 45 per cent. In treated and more advanced untreated secondary syphilis, the proportion falls to from 24 to 20 per cent (A tabular summary of various reports up to 1936 is given by E. Lomholt, 1936) This may be regarded as the basic minimum of neurosyphilis which is not cleared up within the first two or three years of the disease either by the resistance of the patient or reasonably intensive treatment. It is from this group that the tabes and paresis, the vascular accidents and the multiple manifestations of cerebrospinal syphilis are in the later years recruited. It is for the existence of such a group that practitioner and patient who refuse to utilize spinal fluid diagnosis and modern therapeutic measures are responsible

The importance of the spinal fluid examination to the detection of neurosyphilis as an element in general medical and surgical diagnosis, likewise can hardly be overestimated.

An instructive study of this question was that of Stokes and Brown on the interpretation of the medical complaint of stomach trouble in the patient with syphilis. They found that the syphilitic patient with stomach trouble has lesion of the stomach or gastro-intestinal tract in only 10 per cent of 200 unselected cases On the other hand 75 per cent of syphilitic patients who complained of stomach trouble had neurosyphilis, and in 49 per cent of these it was detected or confirmed by spinal fluid examination, though only 44 per cent of the patients had positive blood Wassermann reactions, largely because of previous treatment. Only 10 per cent of the

entire series had had spinal fluid examinations as part of any previous examination, though 49 per cent were positive. Seventy per cent of the patients with persistently negative blood Wassermann reactions, not due to treatment, had positive findings in the spinal fluid.

It is important to note for reemphasis later that the spinal fluid does not invariably indicate the existence of a neurosyphilis, which none the less is present. This is notably the case in certain types of tabes dorsalis, including those presenting Charcot joints and gastric crises, and in the comparatively isolated involvements of vascular neurosyphilis and solitary gumma.

The Time to Do the Spinal Fluid Examination.—The enthusiasm of the clinician is usually when confronted with the exigencies of private practice obliged to make some compromise with circumstances. Theoretically the spinal fluid of the patient with early syphilis should be examined just after the third arsphenamine injection, provided there have been no indications for its earlier performance such as severe headaches meningismus, or symptoms from the cranial nerves. In practice, however the performance of the test at this time is a serious tax upon the relations of physician and patient and hence upon the continuity of the patient's treatment, upon which so much depends. So influential is reaction to lumbar puncture in defeating the aim of treatment as a public health measure that the entire venereal disease practice of Great Britain's Ministry of Health was conducted without reference to it, on the score of its discouraging effect upon the attendance of the worker at clinic. A compromise with the necessities in the individual case can usually be reached by adopting the following principles

1 Information on the state of the spinal fluid should be thought of as part of the preliminary or diagnostic work-up of all patients other than those with primary and secondary syphilis, who have positive blood serologic reactions on first examination. Without the information which it yields, treatment decisions are made in the dark. If puncture is refused and a groping approach is unavoidable one should proceed as if the fluid were abnormal.

2. In early syphilis under treatment, if the blood serologic reactions are still positive at the twenty-fourth week, the spinal fluid should be examined and in any event by the end of the first year before rest period or discharge to observation is granted.

3 In early syphilis treated by intensive foreshortened methods (one to fifteen-day or six to ten week systems) the spinal fluid should be examined before the completion of treatment or as soon as possible thereafter repeated within the year Leifer Chargin and Hyman (1941) examined their patients between the sixth and twelfth month

4 No resistant or fixed positive blood Wassermann or precipitation test can be interpreted or dealt with, without examination of the spinal fluid Such tests frequently mean concealed or asymptomatic neurosyphilis.

5 In persons under treatment in whom blood serologic tests have become repeatedly negative a relapse to positive should be followed by examination of the spinal fluid.

6 The spinal fluid examination must be repeated to determine the progress under treatment of any patient who has neurosyphilitic involvement. The frequency of repetition must be decided by indications in the individual case

7 *Pari passu*, the spinal fluid need not necessarily be examined

(*a*) Yearly or repeatedly as mere routine in patients who responding normally to effective treatment, have negative fluid findings with negative blood when treatment is completed and they are placed on observation Reasonable

clinical (relapsing type) or serologic indication should exist, for repetitions after the second post treatment year. This is especially applicable to early syphilis. In late syphilis, a negative fluid is almost never followed by a positive.

(b) When the spinal fluid findings cannot influence the course to be pursued in the individual case, e. g., a decompensated cardiovascular syphilitic involvement in which treatment is wholly governed by the cardiovascular status.

(c) In extreme old age regardless of the patient's status.

The Physiology of the Spinal Fluid.—The cerebral ventricles and the meningeal sacs covering the brain and cord contain from 100 to 128 cc. of limpid, waterlike fluid, secreted mainly by the choroid plexus but also receiving some additions from the perivascular channels communicating with the subarachnoid space on the surface of the brain (Howe). Kafka (Jadassohn Handbuch) cites Jacobi as having demonstrated some degree of secretion by the ependyma of the ventricles. While the larger part of the spinal fluid is therefore presumably the secretion product of the choroid plexus, and this structure, therefore, stands as a barrier between the spinal fluid and the blood, there is evidence to show that the condition of the spinal fluid reflects local processes in the meninges as well as the parenchyma of the nervous system and that its content may be modified by substances derived from the blood circulation. For example, Weed showed that in cats circulating meningococci could be carried over into the meninges by the effect of pressure reduction in lumbar puncture. *Spirochaeta pallida* has been repeatedly demonstrated in the spinal fluid with and without serological evidence of involvement. Sekiguchi and Kolmer showed that syphilitic reagin from Wassermann-positive human blood introduced into the vascular circulation of dogs, gave a slightly positive Wassermann reaction on the spinal fluid. The penetration of the spinal fluid by such drugs as iodine (Osborne) and arsphenamine has been repeatedly demonstrated. It has been shown in both Sekiguchi and Kolmer's work and Osborne's studies that secretion of drugs into the spinal canal is increased by a meningitis. It is evident, therefore, that under normal conditions the choroid plexus is the principal source and that only under pathologic conditions is it to be expected that the spinal fluid will contain considerable amounts of substances introduced into the circulation. The work of Weed and Carbett indicates that the injection of hypertonic salt solution into the blood stream dehydrates the nervous system and causes increased reabsorption of spinal fluid, while hypotonic solution causes an increase in the amount of spinal fluid. This observation has been utilized in certain forms of treatment of neurosyphilis. Withdrawal of large amounts of spinal fluid (spinal drainage) can be used as a method of draining the spinal canal and even the parenchyma of the nervous system of micro-organisms and toxic products. The method, for example, has been applied in treating toxic primary optic atrophies due to tryparsamide by repeated spinal drainage.

The spinal fluid secreted by the choroid plexus and other contributors has apparently been shown by Dandy and others to be absorbed through the meningeal vessels into the blood stream. Weed, however, has championed the view that absorption takes place through pacchionian granulations and arachnoid villi.

The rate of secretion of spinal fluid is probably very slow when the hydrostatic system is intact. If, however, puncture or rupture of the membranes occurs, secretion may be greatly accelerated and large quantities of fluid lost, through a very small opening. This consideration makes it extremely important to follow those technical details of lumbar and cisterna puncture which reduce the likelihood of leakage of the spinal fluid to the lowest possible terms. Greene, later confirmed by Shaffer's unpublished experiments, showed that the isolated lumbar sac lost very much less fluid through a puncture made with a conical as distinguished from a wedge or bevel-pointed needle, presumably because the fibers of the dura were separated instead of cut by the former point and spontaneous closure more readily took place. Pitkin has devised a needle point which he believes makes a flapped opening in the dura that closes on withdrawal of the needle. M. O. Nelson has shown that plugging of the opening with catgut reduces the incidence of lumbar puncture headache. These various contributory forms of evidence would seem to indicate that headache following lumbar puncture is the result of leakage and disturbed pressure equilibrium, as suggested by Marie and others. That nervous and other influences, however, affect the tension of the cerebrospinal fluid and may, therefore, contribute to reactions, is indicated by Solomon, Pfeffer and Thompson's observations of the effect of muscular tension and the nervous state of the patient in raising spinal fluid pressure at the time lumbar puncture is performed. Gennerich also has called attention to the relatively greater frequency of puncture reaction in high-strung neurotic patients.

From these considerations it will be apparent that the permeability of the choroid plexus and the meningeal capillaries is the critical point in attempting to introduce medication into the cerebrospinal canal by way of the general circulation. It would appear furthermore, that the amount of any given drug in the spinal fluid is a relative but not an absolute index of the permeability of the parenchyma of the nervous system as a whole. When it is desired to treat the meninges directly with a drug, the irritant effects of that preparation must be considered among the factors in treatment, and the possible "irrigating" effect of stimulating a more rapid secretion and absorption of spinal fluid must be taken into account, together with the effect of the introduced substance (as for instance blood serum in the Swift Ellis treatment) in inducing aseptic meningitis and freer absorption of arsphenamines and other medicaments introduced into the blood stream at the same time.

There exist certain differences in the cytology, composition and reactions of the spinal fluid at different levels, as, for example, in the ventricles and in the lumbar sac. These have been studied by Solomon and Ayer but they do not appear to have attained importance as a source of possible clinical error in diagnosis, except in cases of meningeal block, in which case it may be necessary to obtain specimens at different levels as part of the diagnostic study.

The Essential Tests and Findings—Gross Specimen.—The technic of obtaining spinal fluid for examination is considered on page 318 with a discussion of contraindications, complications and reactions. Adequate study of the spinal fluid after it is drawn is a matter for the laboratory. The operator, however, should observe (1) The color. (2) The pressure. (3) The physical state on withdrawal and after standing. Discoloration of a reddish or brownish tinge is produced by hemorrhage, recent or old. Even a very small trace of blood dims the limpid clearness of the fluid. A clear yellow fluid (xanthochromia) is suggestive of cord tumor. Simple turbidity or opalescence usually evidences a degree of meningitis rarely met with in neurosyphilis and is due to the large numbers of cells of the meningeal exudate. Increases in fluid pressure are observed and are of technical importance as a warning to withdraw fluid slowly and in small quantities, except in rare cases of brain tumor in which the probability of increased pressure should have been foreshadowed by neurological and ophthalmological examinations.

Precise pressure determinations have not, in our experience, been of enough importance to justify the practitioner or syphilis clinic in purchasing or using a manometer. Such equipment, however, is essential to the minutiae of neurological differentiation and for the purpose we recommend the portable jointed glass manometer for measuring the pressure directly, in preference to the mercury manometer (Ayer). Normal pressure readings range from 60 to 150 mm. of spinal fluid (Greenfield and Carmichael) and Baldunn has stated that dangerous complications do not arise if the cerebrospinal fluid pressure is not allowed to fall below 180 mm., even in a case in which excessive intracranial tension is present or feared.

Pressure measurements taken under ordinary condition or following painful punctures in nervous and frightened patients are untrustworthy. Marked reductions in the rate of flow are usually without diagnostic significance so far as syphilis is concerned, and indicate more often some obstruction of the opening of the needle or are dependent on the bore of the instrument.

Interpretation of Spinal Fluid Findings.—The spinal fluid as sent to the laboratory for test should be fresh, should be free from blood cells in gross or microscopical amounts unless such were present in it before its removal from the canal, should be sufficient in amount for all tests (8 to 10 cc.) and should be promptly examined. The same precautions in regard to container tubes and labeling should be used as with blood serological tests. Spinal fluid should not be exposed to sunlight (Silker 1941).

Mehrtens, Wyckoff and Davis have found that if blood is removed from spinal fluid by centrifuging, the type of colloidal curve remains the same but is altered in intensity. Loveman and Stocking (1934) found that blood contamination vitiates the Kahn test on the fluid, and Solomon et al. (1934) were able to reconstruct all findings in blood containing specimens, except the serologic test in patients who were also positive on the blood. In patients with general paralysis whose spinal fluid has become negative through treatment, contamination with blood produces a tendency to revert to the original curve. The original colloidal gold curve of spinal fluids experimentally contaminated with the patient's blood can be approximately reconstructed provided hemolysis has not occurred. Colloidal tests in particular are affected by hydrogen ion concentration to some extent, and cell counts to some slight extent, by standing.

Blood in the spinal fluid as a result of puncture, suggests inexperience or technical error. It is advisable however even in a perfect entry to allow at least 30 drops of spinal fluid to flow from the needle before the collection of the fluid into the first of the three test tubes is begun. The cell count should be made by the laboratory from the third tube.

Essential Laboratory Tests.—Upon the spinal fluid four absolutely essential tests should be performed for purposes of syphilological diagnosis, as follows:

1. A quantitative Wassermann test, on more than one quantity of fluid (0.2 and 1 cc.) is generally accepted as preferable to the precipitation tests on spinal fluid which are still in the investigative stage. The Reiter spirochetal antigen is reported to be highly specific in spinal fluid serology. The quantitative Kolmer test is in our experience the most satisfactory.

2. A globulin estimation which may be either a Pandy, Noguchi or Nonne for ordinary purposes, but which will probably be ultimately some form of total protein determination.

3. A cell count, which distinguishes lymphocytes and polymorphonuclears if present and identifies red blood cells.

4. A colloidal test, upon which much of the differential prognosis depends. For this purpose the gum tests with benzoin or mastic are preferable to the usual colloidal gold tests, which are well performed by very few laboratories.

Eagle (text 1937) and Moore (treatment, 1941) in recent writings tend to minimize the clinical importance of colloidal tests in the differentiation of types of neurosyphilis, and to suggest the possible substitution of total protein and globulin-albumen estimations as simpler and more trustworthy. With O'Leary' (1944) objections to this proposed simplification we are essentially in accord. The technic of estimating albumin-globulin ratios and total protein content of the spinal fluid still contains many elements of uncertainty to be ironed out, as can easily be recognized in the surprising reports received from otherwise competent laboratories even on apparently normal fluid specimens. The colloidal tests have, moreover, become a dependable part of the international language of syphilologists, and about them a large body of clinically usable and effective knowledge has been built up. The translation of that knowledge into terms of protein estimation will require many years of combined clinical and laboratory study such as is not yet even completed for the more easily studied complement fixation and precipitation tests for syphilis on the blood serum. It would seem wiser therefore if for no other reason than that of universality of usage and reasonably demonstrated dependability with a known margin of error to continue the use of the simpler colloidal tests, such as the mastic, indefinitely pending the evaluation of protein-globulin relationships in this as well as other fields of medicine.

A quantitative test for sugar (Folin and Wu, Hagedorn and Jensen, Greenfield and Carmichael) need not be done as a routine but is used in differentiation in neurological cases (encephalitis) and should be requested if desired. An increased amount of fluid is required by some methods. The normal ranges between 45 and 85 mg. per 100 cc., usually 48 to 63 mg. according to various authors.

The willingness of physicians to accept or to think in terms of spinal fluid reports containing information only on the Wassermann test, and the practice

of smaller laboratories in reporting on this basis, cannot be too strongly deprecated. All four tests are essential and act as crosschecks on each other. The quantity of fluid routinely obtained should be sufficient for all four tests (8 to 10 cc.) and reports should be rendered on all. No complications in the writer's experience are induced by the obtaining of a sufficient amount of fluid provided the patient is one who should have been punctured for diagnosis at all and provided the fluid is allowed to drip very slowly.

The Spinal Fluid Cell Count.—In the course of neurosyphilitic involvement, especially in the earlier or asymptomatic years, the successive elements in an abnormal picture tend to appear in a more or less constant succession which will be used in describing their significance. A rise in cell count or a slight increase in globulin is the simplest form of reaction observed and the rise in globulin, even more than the cell count, is the most persistent abnormality under treatment, though it is at the same time the most responsive to treatment so far as reduction in the number of cells or amount of globulin is concerned. The cell count differs from the other three standard tests of the fluid in that it must be performed within a short time after the fluid is obtained for accurate results. It is, moreover, vitiated by the presence of any appreciable amount of blood contamination of the fluid even though a means of laking the blood cells be used.

Loren Shaffer carried out a brief but instructive series of unpublished studies on the relation of the cell count of the spinal fluid to the time after withdrawal at which the count was made. He found that the chief error came through sedimentation of the cells on standing. The tube and its contents must be strongly shaken to form a uniform suspension before counting. Great variations may occur through withdrawing fluid from various depths in the test tube, very low counts being obtained from the upper layers and very high counts returned when the fluid is taken from the bottom of the tube. Furthermore, the cells have a tendency to adhere firmly to the walls of the test tube when the fluid has stood for some time. The suspension being uniform, however, cytolytic deterioration seemed to occur at an almost uniform rate of about 20 per cent in each twenty-four hours.

Cell counts on the spinal fluid should in general be made with one of the newer counting chambers such as the Fuchs-Rosenthal. The leukocytes in the fluids are differentiated by staining with Unna polychrome methylene-blue solution which is drawn into the ordinary white blood cell pipet to the first mark (1). The remainder of the pipet is then filled with spinal fluid. Before drawing into the pipet the fluid should be thoroughly shaken in the test tube to assure an even distribution of cells. The count may be made within two or three minutes after the stain is added. All the cells in the entire ruled area of this chamber are counted, the slight dilution with stain being disregarded, and the total divided by 3 for the actual count. If the fluid contains a large number of cells or if a Türk or Thoma-Zeiss chamber is used, the dilutions and count should be made as for a leukocyte count on blood. The addition of acetic acid to the staining mixture is not necessary if polychrome methylene-blue is used, and this stain has the added advantage of affording some differential staining of plasma cells without staining the red blood cells. Moore counts all cells in the field with undiluted fluid and multiplies by 10/9 for accuracy.

The cell count of the spinal fluid is an index of meningeal reaction, that is, of leptomeningitis. It is, therefore, an entirely nonspecific finding and no diagnosis of syphilis of the nervous system can ever be based exclusively upon a rise in the cell count of the spinal fluid. None the less, in conjunction with other clinical and serological evidence, even a very slight rise in cells may be quite significant. Inasmuch as meningeal reaction is one of the earliest forms of pathologic change in many neurosyphilitic processes, the cell count assumes great importance as a warning of trouble, actual or impending.

The typical cell of the spinal fluid in neurosyphilis is the small lymphocyte as distinguished from the polymorphonuclear leukocyte of other forms of meningitis and early poliomyelitis.

Too much emphasis should not be laid on this point. Large lymphocytes may be present to the extent of 80 per cent and in high cell counts polymorphonuclears may reach 3 to 30 per cent, the latter in intraspinally treated patients or after repeated puncture without serious significance. Plasma cells appear at times in the fluid of paresis but are not diagnostic. Squamous endothelium from the subarachnoid space may be disregarded.

The absolutely normal count ranges from 1 to 3 lymphocytes per cu. mm., but an upper limit of 4 cells may be regarded as within the range of normal. Nonne places the upper limit at 5 cells, Greenfield and Carmichael at 3 cells, the presence of 4 cells per cu. mm. in a good specimen being suspicious. So far as syphilis is concerned, cell counts of from 5 to 10 lymphocytes per cu. mm. are the very definite beginnings of the abnormal, and cell counts above 10 are absolutely abnormal. In the examination of the spinal fluid of persons known to have syphilis and to be either within the first two or three months of the disease or under the influence of treatment, slight increases in cell count are distinctly significant. Thus a patient with early secondaries who, following his first 2 or 3 arsphenamine injections, has a cell count ranging from 6 to 10, is showing distinctly suspicious evidence of meningeal reaction. Such a count demands a reexamination of the spinal fluid before he is placed on any form of rest interval. Counts of this type are also obtained in the first spinal fluid examination of a treated patient with early syphilis when this is examined from twelve to eighteen months after the onset of the infection. Under these circumstances they cannot be regarded as normal and warn of the possibility that as soon as a rest period is allowed the patient may suffer some form of neurosyphilitic relapse.

The very definitely abnormal cell counts in neurosyphilis range from 10 to 1500 cells per cu. mm. and even higher. In the special type of syphilitic leptomeningitis associated with prenatal syphilis, the cell counts may be so high as to resemble those of a purulent meningitis and the large number of cells may produce an actual turbidity of the spinal fluid. High cell counts (up to 1000) also occur occasionally in the basilar meningitis of early syphilis and neurorelapse. Very low cell counts may be associated with grave processes, and counts of 2 to 7 cells with strongly and persistently positive Wassermann reactions on the fluid. The independence of the meningeal phase of neurosyphilis and its greater responsiveness to treatment are illustrated by the observed return of cell counts to normal without notable improvement in either other fluid or blood findings, or of symptoms. The average range of cell counts in active neurosyphilis is from 12 to 100, the larger number of the cases falling in the range between 24 and 50. Ravaut and Boulin, cited by Eagle, believe the lymphocyte and small mononuclear cell are representative of mild meningeal reaction, large mononuclear and plasma cells appearing in the more serious parenchymatous involvements including paresis.

The height of the cell count has a certain prognostic significance, and it is possible to show quite definitely that a spinal fluid with a strongly positive Wassermann reaction and a low cell count has a less favorable prognosis than a similar fluid with a high cell count. The cell count is subject to variation after treatment in the form of increases in the count—coming on the second, third and fourth weeks after treatment is initiated and having therefore presumably the character of a Herxheimer reaction or therapeutic flare-up. Quite marked ups and downs in count may occur in serial punctures or be induced by treatment with or without so-called "spinal drainage" ("seesaw counts"). Illustrations of these types appear in Chapter XX.

The Globulin Estimation on the Spinal Fluid.—The increase in the protein of the spinal fluid in pathologic processes is presumably another phase of the meningitis and as such is entirely nonspecific in character It is therefore impossible to prove the existence of a syphilis of the nervous system by an increase in globulin *per se* The globulin estimation has only a limited diagnostic significance but increasing emphasis is being placed on its prognostic value. A total protein estimation thus becomes a very helpful guide to the progress of a treated neurosyphilitic case

A good many objections may be offered to globulin tests as guides to spinal fluid abnormality Those in common use are qualitative rather than quantitative, do not give clue to the albumin-globulin ratio, and of course give no total protein estimation. None the less, their comparative convenience makes such procedures as the Nonne ammonium sulphat precipitation, the Pandy phenol test and the Noguchi butyric acid test still popular for ordinary laboratory purposes. They are usually returned in reports as negative 1 plus or 2 plus, and more exact readings can be obtained by centrifuging graduated capillary tubes (Jadassohn Handbuch) Lange (1930) reviews the precipitation methods. Nephelometric equipment is expensive, requires experienced handling and gives only qualified results. The normal reading according t various authors ranges (Hinrichsen, 1941) from 25 to 75 mg. per cent. The micro-Kjeldahl method remains the standard of reference. A colorimeter method using sulfosalicylic acid is being increasingly used.

The Colloidal Test on the Spinal Fluid.—It is a little difficult for the clinician to realize that the colloidal test, like the cell count and the globulin estimation, is quite largely nonspecific in character and that it is impossible absolutely to confirm or negate a diagnosis of yphilis by this test alone. None the less, the colloidal tests furnish better evidence of the existence and character of a syphilitic involvement of the nervous system than any other of the tests except the Wassermann In the performance of these tests, whether by the use of colloidal gold, colloidal benzoin or colloidal mastic, a series of tubes, 10 in number in the gold and mastic tests and 15 in number in the benzoin test, contain the colloidal suspension, and a series of color or turbidity changes are induced which are expressed by a series of numerals. Thus, an absolutely normal colloidal test with the gold or mastic technic is read as a series of 10 zeros, 0000000000 A negative colloidal benzoin test, on the other hand may read as a series of 15 zeros or there may be a change in the middle portion of the series so that it reads as follows 000 000 033,310 000 A certain amount of variation from the absolutely zero and negative curve is allowable and a mastic of 1100000000 is regarded as negative. This is, in a sense, a nonspecific margin. A gold or mastic test of 0112100000 must be regarded as indeterminate (no reading over 2)

The colloidal gold or gold sol test, discovered by Lange in 1912, was the outcome of Zsigmondi' studies of the ction of albumins on colloidal gold suspension. It is purely an empiric test, apparently expressive of the concentration and physical state of the globulin in the spinal fluid. The work of the English investigators, Wright and Kermack, and also of Shaffer would show that the hydrogen ion concentration plays highly important part in determining the types of precipitation produced by spinal fluid in colloidal benzoin or colloidal gold solution. There are seemingly two substances in spinal fluid causing precipitation of colloidal solution. The substance causing precipitation in zones 2 and 3 acts at lower pH value than that which causes precipitation in zone 1. The factors determining these zones are fixed by the technic of the tests and are dependent on the alkalinity of the spinal fluid, the pH of the colloidal solution and the grade of dilutions of the spinal fluid. While this work gives physicochemical explanation of the precipitation, the true nature of the precipitating substances is as yet undetermined, except that they seem to be contained in the globulin or pseudoglobulin fractions of the spinal fluid. The colloidal benzoin test, introduced by Guillain, Laroche and Lechelle, with modifica-

tion advised by Wright and Kermack in the preparation of the alcoholic extract of gum benzoin, is a very satisfactory test, requiring slightly more spinal fluid than the gold or mastic. The mastic test, devised by Emanuel in 1915 and described by Cutting, is a relatively simple and trustworthy test which is used routinely in the laboratory of the Johns Hopkins Syphilis Clinic and in our own laboratory.

We personally feel that under ordinary conditions of performance mastic or benzoin should replace colloidal gold, for the gold reagent is relatively difficult to prepare and only in the hands of occasional laboratory experts or very experienced technicians gives constant and reliable results. The mastic test has a tendency to read slightly toward the paretic side but with a little experience this can be interpreted and one escapes entirely the repeated fluctuations and "humpy" and uninterpretable results too often returned by the gold test.

The Paretic and Luetic "Zones."—The two types of the positive colloidal test which are of importance in the interpretation of neurosyphilis are the so-called "first" and "second zone" or "paretic" and "luetic" curves. The so-called "paretic or first-zone curve" as represented in the numerical form always reads high to the left. In other words, in the colloidal gold test a typical paretic curve would be 5555432100. In the benzoin test it reads 333,333,332,100,330. In the mastic test the readings in the first-zone curve may range from 3333321000 to 5555531000. The first zone test is the best defined and most distinctive in all three procedures. The second zone test is apt to be indeterminate with the benzoin and mastic methods. Colloidal tests are capable of expressing a certain degree of intensity of reaction so that a paretic first zone test may read 2222100000, a curve of much less intensity than one of 5555432100. Such changes may occur under treatment and they are also well known to constitute fortuitous variations in successive readings under varying physiologic and laboratory conditions. The luetic or syphilitic curve, an accompaniment of other forms of neurosyphilis than paresis, reads in all three types of test, "high in the middle and low at both ends." Thus, a typically intense gold sol test would read 0124554100. Milder types of this curve would not reach 5 on the middle tubes.

Other Types of Curves.—Various atypical curves are observed from time to time in the examination of the spinal fluid of all patients, whether they have syphilis or not, and these variations can only be discounted by experience. Atypical curves may have one or two high digits at the left with marked irregularities throughout the remainder of the series. Tests with no reading above 2 and sometimes even frankly negative tests must be regarded, in accordance with the circumstances of the case, as indeterminate in character and subject to special interpretation.

A third type of curve occasionally seen with gold sol and benzoin in patients who have coincident syphilis with other diseases of the nervous system is high on the right, the so-called "meningitic curve" (0001233345) which is without significance as regards the diagnosis of neurosyphilis, except in a negative way. Its occurrence with slight increases of cell count and protein with negative Wassermann on fluid and blood suggests so-called "multiple sclerosis."

It is extremely important to emphasize, in dealing with the colloidal tests, that, like all serological procedures, they are subject to error and that a single test which conflicts with the clinical facts must not therefore be accepted as gospel. Rayner in 2100 spinal fluids obtained best agreement between gold and mastic tests (91 per cent) with mastic and benzoin agreeing in 81 per cent. He rates the benzoin as the most sensitive procedure. In labeling a certain type, such as zone 1 as "paretic," emphasis must be placed on the fact that

while a paretic curve is invariably of serious prognostic significance, it does not by any means invariably mean that the patient is destined for a paretic outcome In fact, the interpretation of a paretic curve is sometimes, especially in early syphilis, impossible at the outset and must depend on the repetition of the finding, on its response to treatment and most especially on its relation to other items in the four serological tests on the fluid and the serological tests on the blood in both the original and subsequent examinations Notwithstanding this necessity for cautious interpretation the first zone colloidal test in its presence or absence is the one most important single prognostic item in the spinal fluid examination with respect to syphilis.

The Spinal Fluid Wassermann and Precipitation Tests.—The spinal fluid Wassermann test is the most specific test in the entire series and the only one which points, when definitely positive directly to the diagnosis of syphilis. It should invariably as has been said be performed by some type of quantitative procedure, of which we personally can commend the Kolmer It is essential to do a quantitative test because in the spinal fluid the Wassermann reaction may not appear positive until the larger amounts of fluid are employed. This is especially true very early in the disease when the meningeal reaction is the chief pathologic phenomenon and likewise quite late in the disease when the entire neurosyphilitic process is dying out. No physician therefore should ever be content to receive from the laboratory the simple statement that the Wassermann reaction on the spinal fluid is positive or negative. It is essential in interpreting the prognostic significance that he know on how much fluid within the range of 0.2 to 1 cc. the Wassermann reaction is positive. The quantity of fluid used is five to ten times that of the serum in the blood Wassermann test, which greatly increases its value in the detection of syphilis. The fluid is anticomplementary only when contaminated with bacteria (Harrison)

While in all probability precipitation procedure on the spinal fluid will ultimately challenge, if it does not displace, the Wassermann procedure it cannot be said that a sufficient body of information has accumulated as yet to permit the substitution of one for the other at this time, or even to recommend that, except for study purposes, both tests be performed in the routine laboratory

The Positive Spinal Fluid Wassermann Test.—Considerable variation in the degree of positiveness of the Wassermann reaction on the spinal fluid in various types of neurosyphilis occurs. A fluid may be Wassermann negative throughout in an active progressing neurosyphilis In early neurosyphilis associated with the primary and early secondary systemic lesions in which the pathologic changes are almost entirely meningeal and vascular the Wassermann test is negative at the outset, and in the small amounts of fluid even later It may only begin to be positive in amounts as high as 0 8 and 1 cc or in the first tube or two of the Kolmer test (40000) On the other hand strong positives may occasionally be obtained throughout all concentrations in very early cases. In late neurosyphilis of the tabetic type, while the test may be negative on 0 2 cc., it seldom fails to be partially positive on 0 4 or 0.5 cc., and is usually strongly positive on 1 cc The literature shows 54 per cent positive fluids in tabes (Browning and Mackenzie) In diffuse neurosyphilis ("cerebrospinal" syphilis) the proportion of strong positives in the smaller amounts of fluid is high (80 per cent, Browning and Mackenzie) In typical paretic neurosyphilis it is almost a reflection on the sensitiveness of the test

if it is not strongly positive throughout all concentrations. In cases confirmed by autopsy Mott found 98 per cent positive in 1910 Browning and Mackenzie 91 per cent in clinical paresis, in 1921 In preponderantly or purely vascular syphilis, on the other hand the Wassermann reaction on the fluid is frequently negative in all concentrations, and persistently so. In general it has been our experience that strongly positive Wassermann reactions on all concentrations of the fluid persisting through repeated examinations of the fluid and in spite of vigorous treatment have a peculiar gravity and seem to be associated with those parenchymatous involvements that express themselves clinically as general paresis. It is this trend of observation in our own experience which leads us, perhaps without adequate anatomical justification, to interpret the positive Wassermann reaction in the spinal fluid in untreated cases as a rough index of the grade of parenchymatous change and to consider that complete and persistent negativity with convincing evidence of an active neurosyphilis suggests vascular involvement. Such differentiations should not be carried too far The types of active neurosyphilis now known to be associated with a practically normal spinal fluid to be alluded to presently must, of course be included in the group in which the Wassermann test is no guide to the presence or absence of specific involvement.

The False Positive Spinal Fluid Wassermann Test.—In spite of the superior accuracy of the spinal fluid Wassermann procedure, undoubted false positives, both technical and biological do occur Kolmer endorses Boerner and Lukens's discovery of the use of egg albumen (1941) added to the fluid to prevent false positives in his test.

The technical false positive is perhaps the easier to recognize because of the cross check afforded by the other three tests performed on the fluid. A fluid absolutely normal to protein, colloidal test and cell count, with a strongly positive Wassermann reaction on one or all concentrations, is almost undoubtedly a technical false positive and should be repeated and rechecked against clinical findings before anything decisive is done. Biological false positives were reported by Zadek in 1918 in 5 cases of meningitis and in 1927 Zange summarized the literature since Zadek's report. Schaffle and Riesenberg (1928) added to the possible sources of error tuberculous and other forms of meningitis, especially purulent meningitis following otitis media. Cerebral neoplasms and medullary tumor cases have been reported by Simpson and Loewenberg. Malcolm reports 8 atypical Wassermann reactions in 846 spinal fluids, of which only 1 however, was positive with the Kolmer test (cerebral tumor) In this series were cases of bulbar paralysis, encephalitis lethargica, anterior poliomyelitis and tuberculous meningitis. Schaffle and Riesenberg's cases included 8 nonsyphilitic cases, 4 with pulmonary tuberculosis, 6 of the fluids containing tubercle bacilli and 1 a traumatic meningitis with intracellular diplococci. McLean and Munger (1936) reported false positives in encephalomalacia, streptococcus septicemia, electrical burn, extrathecal pneumonitis, various injuries, multiple sclerosis. Kuske (1936) found no positives in latent syphilis and gonorrhea treated with malaria. It appears that the presence of micro-organisms predisposes to a false result. True nonspecific positives were seen in 2 cases of influenzal encephalitis. The presence of small amounts of seropositive blood may produce positives.

Interpretation of the Four Tests.—Nothing is more important than for the clinician using the spinal fluid findings in the study of syphilis whether in diagnosis, prognosis, or treatment, to realize that it is the ensemble which the tests performed on the fluid present, plus the blood serological findings and results of the physical and neurological examination and not the individual elements, which make the diagnostic picture and decide the issue Objections raised against the specificity of the four tests individually thus lose their force if clinical experience shows that certain combinations of them are presumptive evidence of one or another state of affairs in the nervous

system It is the importance of interrelation and cross interpretation of all the four tests in terms of each other which makes spinal fluid examinations of comparatively little value that do not include a cell count, or which consist of a Wassermann test on one concentration only which omit the colloidal reaction or are unaccompanied by blood serological neurological and if possible ophthalmological findings.* Worthless spinal fluid reports, covering a battery of tests impressive on paper but so internally conflicting as to be obviously erroneous and uninterpretable are still a distressingly frequent source of consultant s headache

Rating the four fluid findings in order of their general significance we would place the Wassermann reaction first the cell count next, the properly performed colloidal test third and the globulin estimation last in order of importance in reaching a conclusion as to the status of a neurosyphilitic infection No one of these elements, not even the Wassermann reaction can stand alone without question.

Interpretation of the So-called "Normal" or "Negative" Spinal Fluid.—The normal spinal fluid typically reads as follows Wassermann reaction negative on 0.2 and 1 cc or Kolmer Wassermann, 0000 globulin present in normal amount cell count, 3 colloidal test (gold or mastic) 0000000000 The normal spinal fluid while an important index of the absence of neurosyphilis, can never be accepted as absolute evidence that the nervous system is not involved by the disease Both active as well as arrested neurosyphilis may present completely and persistently negative spinal fluid to all four tests This, as Solomon has pointed out, and our own experience confirms, is particularly true of vascular neurosyphilis, of those forms of tabes dorsalis associated with gastric crises, Charcot joints and trophic ulcers, of cerebral nerve palsies, cerebral gumma, syphilitic epilepsy Erb s syphilitic spastic paraplegia and nonparetic syphilitic psychoses As previously stated it is even possible for the spinal fluid to contain the *Spirochaeta pallida* and yet be entirely negative to all four tests It may be said, however in spite of these qualifying remarks, that the negative spinal fluid is better presumptive evidence of the absence of syphilis in the neurological field than is the negative blood Wassermann reaction in general medicine It may moreover be said that a negative spinal fluid even in the presence of a neurological condition, almost excludes general paresis from the diagnosis. The question of the existence of seronegative paresis is as yet undecided, but there are some indications that general paresis in a preponderantly vascular phase may be almost if not quite seronegative in the spinal fluid, at least after treatment, and yet still be active and symptomatically progressive. Cases of this sort, however are so rare that they need hardly enter into the diagnostic rules applicable to ordinary practice

Interpretation of the Positive or Abnormal Spinal Fluid.—Emphasis has already been placed upon the significance of slight grades of meningeal reaction in spinal fluids obtained early in the course of a syphilitic infection whether in treated or untreated patients. An even greater emphasis in the interpretation of spinal fluid serology should be placed upon what we now label "the red flag."

This combination of the strongly positive spinal fluid Wassermann with a moderate or marked increase in cell count, a sharp but not excessive rise in globulin and a first zone colloidal test, especially when it occurs in conjunction

* These interrelations are more fully discussed in the various sections on early and late neurosyphilis

with a strongly positive blood serological test is, like the rattle of the rattle snake a warning of something serious to come This type of fluid is, of course the earmark of parenchymatous neurosyphilis of the paretic type and it like wise accompanies the so-called "neurorecurrence or acute flare-up of neurosyphilis that develops following suspension of treatment when an abnormal spinal fluid has not been recognized by previous examinations. It is impossible to overemphasize to the physician the seriousness of this spinal fluid picture

Fig 47

Fluids of this type resembling the preceding, but in which the first-zone gold sol reaction is of great intensity are almost invariably paretic, though the fluid picture must be interpreted in terms of the neurological picture Early clinical signs re pt to be present.

NO TIME FOR "NEO" NOW TRYPARSAMIDE? FEVER?

It is an immediate and unescapable warning that only the most effective and intensive of modern methods of treatment will be of any avail in checking the process going on in the nervous system Patients who up to this point have been treated by less intensive methods must, upon the appearance of this "red flag," be considered as candidates for tryparsamide and fever therapy unless they make an immediate response to a great increase in the intensity of standard treatment measures Whenever such a spinal fluid appears

/// 1.0

This is the fluid of acute meningovasculoparenchymatous early neurosyphilis with the meningeal phase especially prominent. It is not uncommon in the so-called "neurorecurrence" after inadequate treatment. Such cases may show symptoms of basilar meningitis—headache, dizziness, palsies, etc., but do not necessarily do so. It is this type of fluid in particular which calls for intensive treatment if the process is not to go on to an unfavorable outcome. The response is usually good. In late syphilis this type of spinal fluid may be associated with rapidly progressive cerebrospinal involvement or general paresis.

TREATMENT MUST BE INTENSIFIED "RED FLAG"

repeated examinations, the first repetition within an interval of three months at the utmost after the first test, are absolutely essential as treatment controls Once the physician in ordinary practice learns to seek for and properly interpret this 'red flag" or warning picture in the spinal fluid, grave neurosyphilis, and general paresis in particular can be greatly reduced in frequency

A Convenient Desk Card.— Recent American writers on neurosyphilis including the Cooperative Clinical Group, have employed in their discussions

the prognostic grading or typing of spinal fluid originally suggested by Moore and Hopkins (1933) This condensation gives in highly practical form the characteristics of three grades of spinal fluid abnormality observed in various

In this patient the meningeal phase is uppermost and the outlook for a favorable response is good. Such fluids are common in early syphilis. It is possible that a marked vascular element will be found to underlie this picture, and fluid of this type during latency is essentially that of a meningovascular syphilis. Gummatous pachymeningitis of the cortex may present similar picture, but with much less meningeal reaction.

*Colloidal mastic or gold, preferably the former
†10–20 large lymphocytes and polymorphonuclears may be present.

lose sight of the fact, repeatedly emphasized that neurosyphilis can exist and progress in the presence of a completely normal spinal fluid and negative serologic tests on the blood

A spinal fluid report which always seems to be interpreted with great difficulty is shown in Fig 52. Granted that the blood Wassermann reaction in this case is negative thus is the fluid of so-called multiple sclerosis and is not at all diagnostic of neurosyphilis, in spite of the first zone colloidal test. A mere slight rise in cell count (7 to 15 cells) with a slight increase in globulin and negative Wassermann and colloidal tests occurs as an accompaniment of a good many systemic infections, as Herrick and Dannenberg have shown

This is not uncommon spinal fluid picture absolutely asymptomatic, serologically negative latent syphilis. There is moderate grade of meningeal reaction. The gold sol suggests the possibility of fa orable response to treatment.

THE REASON FOR ROUTINE SPINAL FLUID EXAMINATION

and must be interpreted in conjunction with the case. Occasionally there seems to be a tendency for partially or weakly positive Wassermann reactions to appear in the spinal fluid of patients with lethargic encephalitis, a fact which is sometimes the source of a good deal of difficulty in differentiation from general paresis. Anticomplementary Kolmer reactions on the spinal fluid and so-called "humpy Kolmer tests (04021) are sometimes quite difficult of interpretation but usually should be regarded as positive.

This fluid is seldom syphilitic. It is much more suggestive of multiple sclerosis. It must be said, however that t times defective batch of gold solution will yield crops of first-zone curves that cannot be trusted. With luetic curve (0134431100) this fluid ould be entirely compatible th a diagnosis of early meningovascular lues in the primary or secondary stage, provided it is supported by other findings. It would also accord with diagnosis of either early tabes, or lat degenerative type of tabes, often associated with gastric crises.

MULTIPLE SCLEROSIS MAY DECEIVE BY NONSPECIFIC TREATMENT RESPONSE

It cannot be overemphasized that the spinal fluid examination can never yield its best diagnostic possibilities when interpreted alone. It is part of the general medical and neurological examination of every patient who has syph ilis, and only in conjunction with findings on examination and the coincident serological tests on the blood can its real significance be evaluated. It is proper too, to reemphasize the fact that the blood may be serologically negative and the spinal fluid present definite evidence of neurosyphilis. Accordingly a spinal fluid examination supplies part of the necessary information for the

full interpretation of seronegative latent syphilis and of the condition of patients in whom the diagnosis of syphilis, while supported by darkfield or clinical evidence has never been verified by serological test. Equal emphasis should be placed upon the positive necessity for a spinal fluid examination of all patients whose supposed state of latency has been diagnosed by the strongly positive blood serological test. Never under any circumstances, should a positive blood test for syphilis be slurred over or minimized (see page 30) The least that it demands once the possibilities of laboratory or biological nonspecific error are eliminated is an examination of the spinal fluid Only in this way will it be possible to detect the red flag at a time when treatment may yield arresting or curative results

("Wassermann positive," etc.)

The Luetin Test.—This cutaneous test proposed by Noguchi now belongs definitely to the past of diagnostic syphilology although its probably important immunity relations still deserve further study At the outset the nonspecific element in the cutaneous allergic phenomena of late syphilis was not appreciated, and interpretations involving it were presently seen to have an insurmountable margin of error Moreover it appears that luetin tests performed with suspensions of cultivated *Spirochaeta pallida* do not appear to give as trustworthy results as do those performed with organisms in suspension with tissue extract such as lung, liver and testis. The more recent publications of Hollander Kolmer Brandt, Gandy and Ambler and of Bessemans (1933) may be consulted by those desiring first-hand information In view of the equivocal and unfavorable reports, organic luetin was refused acceptance for N.N.R. by the Council on Pharmacy and Chemistry on the ground of insufficient evidence of value or safety

CHAPTER V

THE FUNDAMENTAL PRINCIPLES OF TREATMENT

Complexity and the Fundamentals.—The disposition to avoid a section headed "Principles" and to thumb the pages of a presentation until one reaches the routine prescriptions systems and schedules of dosage and intervals which it is fondly imagined will give the desired "practical knowledge of treatment" is one of the most serious mistakes in dealing with the therapy of syphilis that can be imagined.

The therapeutic formulas most widely accepted today are literally in the dust heap tomorrow and large blocks of text are dead before they are born. Witness the transformations involved in the efforts to shrink treatment for early syphilis from 05 weeks to 5 days. In such a rapidly changing field only principles remain to save the distracted doctor's sanity. The chief difficulties in the practitioner's management of syphilis have been found to consist, first, in a relative ignorance of drugs and complications; second, in the tendency to monosymptomatic treatment, especially as exemplified in the ruthless attack upon the positive Wassermann reaction as such; and finally in a tendency to indiscriminate bombardment, as when a mouse sets off the barrage of guns in a wild-animal trap. Unfamiliar with drugs and their dangers, with the purpose for which each is to be used, with the importance or insignificance of the symptoms first presented, and possessed with a laudable desire to do all that duty demands and the patient can pay for, tempered by an unfortunate disposition to stop when lesions heal or surface signs disappear, it is small wonder that the practitioner's treatment for syphilis has in the past decade been a monument to inadequacy early in the disease and to therapeutic furor and overenergetic misapplication in the later phases.

Therapeutic Experimentalism and Impressionism.—The very nature of syphilis sets conditions upon advance in knowledge which the practitioner cannot meet. Years of observation are required for the determination of a therapeutic result. Rigorous controls must be set which even the best organized clinics find it very difficult to carry through. The mere healing of lesions or the momentary betterment of the condition of the patient, instead of symbolizing a lasting and satisfactory therapeutic result, may be only the threshold to failure or disaster, as in the modern problem of Wassermann-fastness, of neurorecurrence and of therapeutic paradox. It is, therefore, particularly unwise to encourage the individual physician with a small experience and a small clientele in the disease to strike out for himself, disregarding precedents and the more massive experience of organized groups and centers of clinical and experimental investigation. Equipped with the principles which these centralized investigations offer him, he can be an invaluable aid in the determination of long-range results through the intimacy and the prolonged character of many of his contacts with patients. On the other hand, his opportunity to serve in this way is reduced to insignificance by the harm he can do

For those interested in the historical philosophy of treatment problems in the United States, reference should be made to pp. 186–189 of the second edition of this book.

Brown that the currently used trypanocidal test for arsphenamine therapeutic efficiency is not satisfactory as test of spirillicidal activity

All these considerations taken together seem to us to indicate strongly the need for stringent disinterested regulatory supervision of products used in the treatment of syphilis. The National Institute of Health of the United States Public Health Service which is responsible for toxicity standards in this country has thus far felt itself unable to take up the problem of therapeutic control.

Clinical Testing of Antisyphilitic Drugs.—It may perhaps serve the useful purpose both of defining the conditions under which drug testing in the syphilological field should be done and impressing the reader with the complexity of the problem, the need for controls and the slowness with which results can be evaluated, if we summarize here in tabular form more than decade of experience in testing drugs in the treatment of syphilis, together with impressions gained from conversations with authorities on various aspects of the problem.

1 The originator of preparation for the treatment of syphilis should be prepared to stat the composition and general method of manufacture to the clinician and responsible agencies that he approaches, though at the outset this may be done in confidence.

2. The first one to t years of the li history of an adequately studied syphilotherapeutic agent are spent in animal studies. Those relating t curative effect are, of course, the most laborious, protracted and expensive. Animal investigations include (a) animal toxicity tests by various routes of administration which should have been made and the results stated in writing before clinical trial is considered (b) reactions which should have been studied in animals, including effects on the skin, the vital organs and the eliminative mechanism, as well as the injected site if the drug is given intramuscularly ( ) the trypanocidal index should have been obtained, if the drug acts on these orga isms (d) spirillicidal effect, if directly observable, should have been studied in rabbits (e) optimum dosage and therapeutic indices should have been determined; (f) healing effects should be studied (g) curative action should be determined, not by single set of short-lived experiments, but by multiple animal passages through several generations, using the modern laboratory devices of lymph node transplant, emulsions and organ hash.

3. While these studies are in progress, stability of the drug under market conditions should have been observed and loss of therapeutic efficiency proved or negated.

4 The first test on man should begin with ( ) the definition of the field of application of the drug (for instance, tryparsamide in neurosyphilis as distinguished from an arsphenamine in early syphilis) (b) the originator and staff should test the toxicity for man of the first doses upon themselves, ( ) decision as to the amount and character of clinical material required should be reached early and studies should not be made by individuals or clinics insufficiently supplied with the necessary clinical material.

5 No other preparation should be used simultaneously with the drug under test. This requirement greatly increases the difficulties of clinical testing, because it is well recognized as an improper use of human material and an abuse of the Public Health responsibilities to test alone for example nonspirillicidal drug on considerable series of patients with early infectious syphilis (chancre and secondaries) except under strict quarantine and hospital control.

6 Adequate medical appraisal of the *status praesens* of all human subjects with proper and complet records must be vailable t the start. Observations must be made on reactions t administration both local and general.

Further observations should include studies of

7 The rate of disappearance of organism from active lesions.

8. Healing and symptomatic response

9 Rate of reversal of serological reactions in early syphilis, latent syphilis and other special aspects.

10. Therapeutic shock and flare-up.

11 Therapeutic paradox.

12. Serological relapse on blood and spinal fluid.

13 Clinical and especially infectious relapse.

14 Proportion of serologically resistant cases.

15 General tolerance of treatment.

16. Elimination, storage and penetration studies ma

17 Optimum dosage nd interval in man

18. Proper duration of treatment in man.

19. Reestimation of the field of application and of risk of reaction in man.

20. Correlation of results in animals and man.

21. Annual routine reexamination of treated patients. This necessitates extraordinary and rarely available follow-up facilities. The time required for adequate study of a preparation ranges from ninety days (to determine surface spirillicidal action) to the second decade and longer (to determine ultimate curative action).

22. No citation of results or exploitation of drug without clinician's approval based on reports at intervals, say of two, five and ten years.

23. Submission, in the United States, to the Council on Pharmacy and Chemistry after the second year and to the United States Public Health Service before tests on man are begun.

24. Consideration and solution, if possible, of those special problems and difficulties inevitably concerned especially with drugs acting upon the resistance mechanism rather than the organism (no spirillicidal effect).

This may be concerned as a rather idealistic program for controlling the use of drugs in the treatment of syphilis. It is perhaps safe to say that very few preparations in common use today would have survived such complete investigation or have, indeed, ever been subjected to it. It represents, none the less, an ideal to strive for and one applicable without too great difficulty to practically all preparations where the motive underlying their exploitation is scientific and humane rather than commercial.

Principles and methods of evaluation of antisyphilitic treatment are further discussed by Moore, Hardy, Robinson and Eagle (1936), Snodgrass (1938), Stokes and Beerman (1937), Eagle, toxicity-dosage relations (1944), Stokes, intensified treatment (1942), and Stokes, Beerman, and Wammock (1945).

PHYSICIAN-PATIENT RELATIONS AND PROBLEMS

Appraisal of the Case.—Before treatment is begun, not only is it necessary *to know with certainty that the patient has the disease, but it is essential to* know in exactly what way he has been affected by it. Not only must he be appraised as to his present status, but his possible therapeutic response must be carefully evaluated and his ability to tolerate ideal procedure, or various compromises with it from the standpoint of complications, must be carefully considered. Incomplete examination is the curse of syphilological treatment as it is of diagnosis today. Too often the physician, proceeding on the basis of a single suspicion-arouser, such as the positive blood Wassermann reaction, gives a heavy dose of one of the most powerful drugs in existence. Suppose there is a sluggish pupil that he did not see or a buzzing ear that he did not ask about? In a few hours the patient is perhaps in convulsions or deaf for life, perhaps he is merely anuric or paraplegic. Perhaps, to descend to the minor frequencies in accidents, he just vomits and can't stop, or has a chill, a high fever and a rash, and repeats the performance time after time until the discouraged physician calls the detail man in consultation or sends the drug supply back to the manufacturer with angry words. Perhaps, with a silent resolve, he falls back on "mixed treatment," not realizing that that is precisely what he has been using from the start. The specialist himself can with good reason speak apologetically and with humility of this inevitable problem of the correct appraisal of the case. He well realizes how frequently he himself falls to meet the full demands of conscience and sound practice in this regard. If one who devotes the larger part of his time to the problem must more than once take himself to task for some unrecognized though obvious fact in the patient's make-up that could have been identified by examination but which he has overlooked, how much more frequently must the harder pressed practicing physician, the specialist in other fields and the physician who for one reason or another must "take a stab at it," fail to live up to his first and most essential requirement. No matter how a syphilitic infection is recognized

whether by a complaint of falling hair an accidental or a routine discovery of a positive blood serological test, a "hot spot" in the family history or a thumping aneurysm presenting through the sternum—the patient must be examined and examined from crown to sole Only in this way can we decide what he needs on the basis of what he has and whether or not he can take it

Weigh the Risks Against the Benefits.—There are risks so serious, especially in the treatment of late cases by intensive methods, that the patient should not be asked to take them. There are benefits so doubtful and methods so double-edged that a hairline judgment can very properly be drawn between the decision to do or not to do It is not infrequently very much better syphilology to withhold than to give a drug, to prescribe rest instead of action and to adopt slow methods instead of fast ones. The ability to resist the spell binding effects of an arsenical miracle is sometimes the real mark of the expert though such a statement must not for a moment be taken to advocate the withholding of an arsenical in the field of its proper and most vital effectiveness, which is particularly the treatment of early syphilis and the control of infectious lesions.

Estimate Impairment and Tolerance—Throughout all of late syphilis the problem of individualization, again to be mentioned can be responsible in its misinterpretation for endless discredit and discouragement in the application of modern therapeutic methods. This is especially true in cardiovascular and neurosyphilis, and visceral, *vide* hepatic disease. It cannot be too frequently reiterated that to consider the capacities as well as the incapacities of the syphilitic patient with respect to treatment is almost the alpha and omega of the late therapeutic problem.

The patient s tolerance of treatment for syphilis has, of course many individual elements and fortunately rests upon a broad base of general ability to receive and profit by almost any even halfway intelligently directed therapeutic measures. Lack of tolerance under the guise of idiosyncrasy is an inescapable problem but it too frequently involves not only the inborn incapacity of the patient but the acquired intolerance that results from misapplied overstrenuous and ill-considered therapeutic measures. The invoking of "idiosyncrasy" to explain bad therapeutic results is a habit into which the most conscientious can easily slip and one which should never be indulged without the most searching self-examination for recognizable and avoidable mistakes in treatment methods. It should be widely understood that there is a way around or a means of forestalling most difficulties in syphilis therapy

The Time Factor—In weighing risks against benefits and even more in deciding upon an objective, the time factor in dealing with syphilis requires constant and reiterated emphasis. When the duration of the infection in the individual case can be ascertained or presumed it becomes an important element in decision as to the required intensity and duration of treatment This is particularly apparent in the effect of time on infectiousness. A patient whose disease is of more than five years duration need rarely if ever be treated by a technic directed solely at the prevention of infectiousness. It is therefore *ipso facto* possible to consider him more as an individual than as a social problem Again one of the serious mistakes of an era of arsphenamine enthusiasm has been the tendency to feel that a syphilitic infection of short duration is more easily cured and requires less treatment than one of a long duration This is the basis of the old concept of abortive cure in early syphilis that has been responsible for much Wassermann fastness, relapse late cardio-

vascular and neurosyphilis. A syphilis of fifty years duration may yield completely in symptomatic response for the remainder of life under treatment which, if applied to a syphilis of six days duration might result in almost unconquerable complications and ultimate disaster

The Age Factor —Experience with the biology of the disease leads to an appreciation of the age factor in a syphilitic infection This amounts practically to an appraisal of the average rate at which an untreated or partially treated syphilitic infection may be expected to produce symptomatically recognizable complications A man of twenty five, who at eighteen had acquired a syphilitic infection would be definitely in the period during which cardiovascular complications, while asymptomatic, could be expected to be in process and to be feared The decision as to the intensity of treatment to be applied in such a situation is based on a life-insurance-like appraisal of the years during which this patient will have the opportunity to suffer from progressive manifestations in this group of structures. It will *ipso facto* be more intense than the treatment of a man acquiring a syphilitic infection at the same age but recognized as absolutely free from symptoms two decades later These considerations are discussed in greater detail under the problems of latency

Therapeutic Shock.—The combination of powerful drug and uninvestigated patient most frequently resolves itself (let us say in one third of reacting cases) into a type of therapeutic explosion with which the practicing physician even today is all too unfamiliar This form of treatment complication or perhaps better therapeutic reaction has been spoken of as the Jarisch Herxheimer effect.

It was first described by Jarisch in 1895 and elaborated in conception by Herxheimer and Krause in 1902. The original effect was observed in the use of mercury injections and consisted in brightening or flare-up of the syphilitic roseola. Jadassohn, in 1895, and Finger in 1910, gave confirmation, the latter observer first noting the much more striking effect of arsphenamine as source of such reaction.

The term "therapeutic shock" used throughout this work impersonalizes the observation but emphasizes its potential gravity and significance, which are often paramount in the later stages of syphilis and in the involvement of vital structures in which local edema and reaction can have serious and even fatal consequences.

The earlier emphasis in discussing this reaction had been mainly upon the flare-up of cutaneous manifestations and the provocative serological response which has been interpreted as phase of the Jarisch-Herxheimer reaction. Only within recent years has it been realized that therapeutic shock takes place in any and every structure involved by syphilis at ll stages of the disease and that it becomes practical therapeutic problem only with the arsphenamines and at times bismuth. Whether or not shock results from the liberation of toxins from destroyed organisms or by irritation of living organisms before their destruction, cannot be regarded as fully established; but the occurrence of the reaction with drugs whose effect is not primarily or rapidly spirillicidal and the occurrence of provocative effect in test involving very probably lysis of spirochetes, seem t support either view the predilections of the interpreter may dictate Illustrations of "Herxheimer effect are given in Figs. 85 to 86.

Prevention of Therapeutic Shock.—Therapeutic shock effects are produced primarily by premature use of the arsphenamines and by overdosage with them. A safe general rule for their prevention in early syphilis, where they are least serious, is to make the initial dose of an arsphenamine never greater

than half the established maximum therapeutic dose In the presence of special symptoms from a particular group of structures such as the eighth nerve the recognition of an early neurosyphilitic involvement and in all late aspects of the disease therapeutic shock is avoided by the device of 'preparatory treatment' or 'preparation' which consists in the initiation of treatment with a slow-acting, relatively nonspirillicidal drug such as mercury or bismuth The length and character of such a preparation are discussed in detail under the chapter devoted to the heavy metals (p 220) *It should* not be understood that heavy metals never produce therapeutic shock, or that arsphenamines cannot be used without producing it. There is some reason to believe that drugs such as bismuth may produce a very appreciable and even serious degree of shock in some cases, and there is no doubt that the arsphenamines, in suitably low and slowly increasing dosage and by a route like the intramuscular which makes for slower absorption can be used without the induction of an appreciable degree of therapeutic shock.

The practitioner should make an effort personally to acquaint himself with this reaction, which comes on usually within the first twelve to twenty four hours after intravenous medication in an early case, by observing the course of the secondary eruption at the named time intervals and taking the temperature of the patient at two-hour intervals in several instances in order to detect the systemic phase of the reaction Delayed shock effect can be observed particularly well in bone lesions and in the symptomatic flare-up of neurosyphilis that occurs from one to four or five weeks after the institution of an intensive form of treatment in late cases. Local edema with systemic and symptomatic exacerbations is the essence of the reaction at all sites and while of no great significance in a chancre, it may be fatal in the wall of a coronary artery or the pinhole opening of a larynx occluded by a gummatous process

Therapeutic shock is, of course familiar in many other conditions besides syphilis, including reaction to tuberculin, t -my and to nonspecific therapeutic measures. The great complexity of the mechanism involved and the *fact that certain of the manifestations, particularly those* associated with hyperemia, have no necessary connection with the medicament or even with the organism concerned, is suggested by the critical and stimulating summary of Bettmann. A reflex vascular mechanism is pparently involved and Böhme called ttention to the accentuation of dermographism which may form part of the process Bohme confirmed and reemphasized Böhmig observation. Böhmig believes the Jarisch-Herxheimer reaction to be an anaphylactic response t antisyphilitic drugs. Matzenauer and also Oppenheim have pointed out that while the Jarisch-Herxheimer effect may be regarded in general as f vorable type of reaction approximating therapeutic inflammation, severe Herxheimer effects produced by overdosage sometimes have deleterious instead of beneficial influence. The importance of possible temporary or permanent vascular injury or hypersusceptibility involved in therapeutic shock may explain the clinical impression that patients subjected to severe therapeutic shock run thereafter stormy course with respect to vascular reactivity dermatitis and the like under subsequent arsphenamine treatment. Milian has recently reiterated his belief that the Jarisch-Herxheimer reaction is form of therapeutic activation of the disease process by the drug employed, and that it should not be made the signal for reduction in subsequent dosage. Houghton has shown that the Kahn reaction in early secondary syphilis, quantitatively measured, parallels the flare-up in the secondary eruption, the range of increased intensity being from 60 Kahn units to 240 Kahn units, following 0 4 Gm. of arsphenamine. He opposes Milian view that the aggravation of clinical symptoms is due to insufficient therapy and believes rather that it is due to liberation of endotoxin from destroyed organisms.

Therapeutic Paradox.—The intense action, particularly of the arsphenamines, produces not only therapeutic shock but a rapidity of healing which

has disadvantages sometimes far exceeding any possible advantage. In early syphilis, rapid healing provided it be accompanied by adequate spirillicidal action, is ideally desirable. In late syphilis rapid healing is tantamount in many cases to a high degree of fibrosis and replacement of organ parenchyma which may have the most serious effects. It was presumably with such considerations in mind that the original directions for the use of arsphenamines, as pointed out by Wile, contained explicit cautions against the indiscriminate use of the drug in late syphilis of the visceral and cardiovascular apparatus. To Wile belongs the distinction of having formally revived these cautions after a decade of indiscriminate enthusiasm and to have pointed out the seriousness of what he has called therapeutic paradox as a general problem of treatment.

A typical example of arsphenamine therapeutic paradox appears in the treatment of syphilitic cirrhosis of the liver. The patient with a markedly enlarged, diffusely involved cirrhotic liver but showing no evidence of portal obstruction, is placed at the outset on arsphenamine treatment, and makes an initial rapid response with improvement in general condition and marked reduction in the size of the liver. This therapeutic gain, however, is too often shortlived. Presently the patient begins to lose ground, the shrinking of the liver by the rapidly developed fibrosis is accompanied by obstruction of portal circulation, ascites appears and serious complications, with perhaps an ultimately fatal outcome, too often ensue. In a case of this sort the rapid healing effects have so seriously interfered with the circulation and function of the liver that by virtually reducing an important viscus to a mass of fibrous tissue, the drug has killed the patient while curing the disease. In coronary and myocardial involvement the rapid advance of myocardial fibrosis and embarrassment of circulation by coronary occlusion is one of the distressing sequels of the too ready use of arsphenamine in syphilitic cardiovascular disease. Deschweinitz has repeatedly emphasized the damage done by fibrotic healing under arsphenamine treatment as applied to ocular syphilis.

Prevention of Therapeutic Paradox.—The remedy for the complication is directly apparent from the logic set forth. In Wile's own words, "Treatment directed to a diseased organ in which the inevitable and ultimate result, both of the disease and of the treatment, is the production of a scar, should be of the type which leads to a slow rather than a rapid process of healing. It seems injudicious to employ in the treatment of any form of syphilitic disease any form of therapy in which the ultimate process of the disease is rapidly anticipated, so to speak, by the effects of the treatment. A gradual resorption seems to result in a better-functioning organ than follows a rapid absorption and disintegration of the disease processes. Such gradual effects can be obtained with mercury and iodide, with the careful use of bismuth and by the arsenicals in greatly reduced and graduated dosage, precisely as in the avoidance of therapeutic shock effect. In other words, postponement of the arsphenamines and the use of preparatory treatment will do away with two of the most serious sources of bad results with which the physician who treats late syphilis must deal.

Envisage an Aim or Objective.—Having examined the patient, and having detected and appraised, so far as possible, his impairment, his tolerance and his susceptibility to therapeutic shock and therapeutic paradox, a conscious, clear-cut effort should be made to formulate the purpose of treatment and to consider the methods best adapted for achieving the end desired.

Intuitive and Experiential Factors.—It is always hard to realize that our vision of what is really happening under treatment is indirect and subject to unknown correction in terms of peculiarities of host and organism, for which we have no means of measurement or detection.

We expect standard results for standard amounts of treatment, as if we were carving block of know hardness with tools of known edge. Instead, we obtain central group of good results, margin of medium results, and a fringe of failures which, when seen in itemized form, looms large. The trend of improvement in treatment methods is less toward sharp-cut cures and failures and more toward increases in average efficiency The syphilologist often evaluates the combination presented by his patient and the organism with which he is infected, in the course of the first few months rather than days of treatment. His intuitive estimate of the situation is often the best background for anticipating and forestalling trouble. He learns to recognize the "mucous membrane relapser the "meningeal relapser the man who thrives on rubs, the patient who easily overtreats, the patient whom nothing can harm, the irritable skin, the phobic mentality and the resistance that nothing can budge These are the priceless assets of experience. The patient who shifts about from one physician to another intolerant of supervison, may lose the benefit of any coordinated and balanced comprehension of his case.

The first decision which must be made in the majority of cases is that of "cure" *versus* arrest. The objective in a youth with a three-day old chancre is completely different from that of the elderly tabetic with ataxia, lightning pains and incontinence. The most striking contrast exists between the ideals and methods of early as distinguished from late treatment and between massive as contrasted with symptomatic methods. A selection of drugs and a technic entirely appropriate to a latent infection with no physical signs to support a positive serological reaction, may be fatal, if applied to a patient with only trifling aortic signs, but the well-defined beginnings of an angina pectoris. The mere difference in the spirillicidal effects of bismuth and neoarsphenamine a matter of less than a week in rate of disappearance of organisms has been blamed in part for an increase of syphilis in France in contrast with its decrease among her neighbors. Innumerable complexities arise in consideration of the influence of treatment on resistance and the disturbance of defensive balance by injudicious and incomplete therapeutic measures The weighing of therapeutic decisions involves not alone the patient himself but the social order his economic and personal status, his habits and his family and friends Errors in judgment, at times apparently not particularly concerned with the individual patient's individual syphilitic involvement, lead, as in the exacerbation of paresis under tryparsamide therapy to the discredit, in the eyes of the inexperienced and uncritical, of the entire fabric of the modern and demonstrably effective control of the disease. Through study of the case, through reading and through consultation the reasonably equipped physician can satisfactorily decide many of these problems for himself provided he recognizes the obligation and makes almost a ritual of its performance It is not too much to say that there is a modern technic whose effectiveness can be expected to range from 50 to 100 per cent for the achievement of every practical therapeutic aim in connection with the disease. To refer the matter to hearsay or to the instructions on the drug wrapper may lead to a catastrophic *dénouement*.

At this point ttention may properly be called to the invaluable abstracts published monthly by the United States Public Health Service in the journal "Venereal Disease Information, subscription to which, at nominal cost, may be made through the Superintendent of Documents, United States Government Printing Office

System *vs.* Individualization.—The trend and experience of the modern public health movement against syphilis seem to be unmistakably toward the recognition of a highly significant principle in syphilotherapeutics Incline to system early and to individualization late." From the League of Nations

and Cooperative Clinical Group studies it will be apparent that practically hard-and fast routines can even be employed in the management of large numbers of patients with syphilis both early and late. Reasonably accurate comparisons between the results of these systems and a process of standard ization which should lead to an ultimate optimum for the drugs available to this generation may be achieved The comparative youth of patients their general good health above all their freedom from the complicating and qualifying disabilities for which syphilis, the wear and tear of life and other diseases, are responsible in their later years, all combine to make the management especially of the primary secondary and latent phases of syphilis more or less of a machine affair conforming closely to certain standards and redu plicable from clinic to clinic and office to office throughout the world

The Organization of Treatment—Clinic *vs* Doctor —The syphilis clinic or other agencies for mass treatment publicly or privately operated are the obvious and natural answer to the growing complexity of syphilis treatment and the evident instrument for system and standardization Simplification, on the other hand tends to the distribution of any form of diagnosis and treatment among the large body of practitioners While the issue as thus drawn applies perhaps to the entire field of medicine in the problem of venereal disease it is acute Here the individual practitioner is now on trial as nowhere else in medicine and nowhere is his dominion harder pressed or more gravely threatened.

The treatment of syphilis in private practice is gravitating into the hands of a limited group within the general body of practitioners. In this group, constituting perhaps 10 to 15 per cent of the physicians of this country lies such hope as exists for an American solution of the problem of venereal disease control dependent upon the individual rather than state or corporate initiative

The Advantages of the Clinic.—By the use of technicians under direction, the clinic can surpass the average physician in technic. If and when foreshort ened intensive methods and fever therapy are widely applied, syphilotherapy will be increasingly centralized and institutionalized Centers can surpass the average physician in physical facilities for a complete examination and appraisal though in the individual case they will rarely except under super human inspiration equal in detailed perfection the decisions of a highly trained expert. For a certain impersonal quality of service and for its short comings in judgment, the clinic can offer the economic advantages of cost lowered by business methods and mass production. Through the use of the same economies it can spend where the practitioner unaided cannot, and can follow the patient maintain scientific record of him and from large series of cases, tests or repeated therapeutic manipulation evaluate in a short time the worth of procedures which the individual cannot determine from less than a lifetime of work in the field Even allowing for an indefinable something which reduces the level of performance of the individual as a cog somewhat below that of the individual acting on his own initiative and on his undivided responsibility we are satisfied from our own observation that the reasonable demands of the movement for the control of venereal disease with respect to syphilis can be met with sufficient completeness for the ultimate extinction of the disease by organizational treatment both in public and in private practice

The Expense of Treatment.—Expense from the standpoint of the patient, is one of the most serious issues in elaborating the treatment of syphilis under

the demands of modern knowledge. Most patients at the age when they acquire the disease are penniless at the foot of the ladder of business and professional success. Years later confronting one of the late complications of the disease, they may have reached the bank president s desk or the financial status of a captain of industry but in the days when effective treatment would have insured their future from the health standpoint, they had neither the free time nor the money for curative management. It is therefore a definite obligation upon the physician at large and upon the syphilotherapist to try to think preventively for the patient in terms which are compatible with his purse.

It is here that "production methods capture the field. For about one dollar per patient visit, a reasonably well-organized clinic for dermatology and syphilis can provide better grade of care than the average doctor can give t $5.00 per visit; and for the cost of the serological tests alone in strictly privat practice clinic can supply the entire three years of the most modern management of syphilis and more than meet the cost of all its services. Analyses of the cost factor have recently been published by Keidel, Bromberg and Davis, Thompson and Brumfield (1936) Goldberg (1938), Brumfield (1939) Beerman (1940) Cornelz (1940) and others. As Stokes has repeatedly said elsewhere syphilological private practice nowadays is literally so far as the early stages of the disease are concerned, capitalizing privacy not performance Even privacy our last hold on the taboo-ridden public, is being endangered by the well-planned equipment hich the modern clinic can furnish. Organization is inevitable in venereal disease control and it remains to no small extent for the physicians responsiveness and interest in the movement t keep him at the head of instead of t the mercy of organization when it assumes its place i the field. I the place therefore, of mere blind opposition and distrust, it is strongly urged on physicians confronted by the encroachments of organized zeal, that they join rather than denounce; and from within, not from without, by constructive cooperation rather than mere indignant opposition they leaven the lump and mold the policy to the conservation of the values of personal and individual medical practice.

The so much *feared* assumption of complete authority and responsibility by the state in the venereal disease field has at least, thus far in this country been more a bugaboo than a fact. Certain functions which the state can easily perform for the practitioner not only constitute no invasion of his individual prerogative but, if refused by the physician, will ultimately lead to his actual replacement for inefficiency Nothing would seem more unwise than for the *individual doctor to refuse to go halfway to meet the state in the working out* of a joint solution The tendency of American public health authority has been to lean over backward in avoiding encroachment on the practitioner s field rather than the reverse and the doctor who rejects the opportunities afforded by the state for protecting and developing his syphilotherapeutic technic, has only himself to blame if he is ultimately replaced What might be denominated "*legitimate functions of the state in present American practice* are considered in the closing chapter

The Use of Consultation —The actual technic of treating syphilis vexatious and even difficult as it sometimes is can be mastered by the majority of practicing physicians and by most medical students in their hospital and intern contacts. It is quite a different matter however to master the general knowledge of the disease *which should underlie many therapeutic decisions* so that there is a definite place in clinical syphilology for what might be called the consultant prescription, especially as applied to late syphilis

The volume of question and answer material on yphilis alone, passing through such department as "Queries and Minor Notes in the Journal of the American Medical Association is evidence of the growing ppreciation by the profession of the need for some form of consultant

service The attempt to answer the questions of physicians seeking consultation by letter in behalf of patients very quickly demonstrates the wide range of problems involved. (See Stokes, Ingraham and Stannard "Two Thousand Questions 1940.) Correspondence is at best only a relatively unsatisfactory medium. The information supplied with the question is often insufficient for the answer which is desired and even when supposedly full information is supplied, it contains serious gaps as, for instance the omission of a colloidal test formula, the presence of blood cells in the spinal fluid, and items regarding the eyegrounds, all of which may be vital to the decision desired It should not, therefore, be imagined that any column or question-and-answer-bureau type of response to the need for consultation in syphilology can be satisfactory or at all substitute for the personal examination of a properly organized special center or individual specialist.

The range of examination necessary in late syphilis is moreover so great that it is *ipso facto* out of the question to study the case properly without facilities rarely available to any one individual. Recognizing this fact, there had developed in Germany at the close of World War I a definite network of consultation centers ("Beratungsstellen"). Centralized facilities are fundamental to the British program and are likewise essential in Scandinavian organization, the oldest and, on the whole the most successful in the world. The great Central Institut in Copenhagen contains a register of all the patients in the country who have syphilis. The United States Public Health Service offered its service to the profession for the evaluation of patients at any of its clinical centers in 1941 Central registries equipped with adequate tabulating machine systems both for the registration of venereally diseased patients, more specifically syphilitic patients, and for the control and check on the practice and follow-up of clinics are being installed in a number of important centers, with the aid of the United States Public Health Service. While as research instruments their efficacy is controversial, there can be no question of their value in the systematization of control of the clinic treatment of the venereal diseases.

Consultation by correspondence should be an important aid to the physician in private practice and Kroll (1943) has described the type of system developed up to that date in California, Connecticut, New York and West Virginia. An attempt to develop such a system in another state however met with a set-back based on the medicolegal responsibilities involved in prescribing treatment for a patient who has not been personally examined by the prescriber It was informally ruled that such procedure in a disease as serious as syphilis might constitute actionable malpractice. Problems of this sort will have to be ironed out by consultation between the legal and public health authorities concerned, and probably do not constitute a serious bar to useful service. The type of material handled and the questions involved in consultation by correspondence for syphilis were critically examined by Stokes, Ingraham Jr and Stannard on the basis of a ten-year collection of material including the consultation service supplied by the Journal of the American Medical Association through "Queries and Minor Notes. Up to 1940 the doctors' questions concerned in order of numerical frequency treatment schedules, the choice, properties, dosages, methods of use, and recommended preparations among drugs serologic tests and their interpretation, treatment reactions; case histories for diagnosis; and various problems involved in the differential diagnosis of syphilis. It was clear that the physician is more interested in late than in early syphilis; that he had little interest in and rudimentary conceptions of the problems of infectiousness, of pregnancy in syphilis, and of prenatal or congenital syphilis. Very few questions were asked concerning the spinal fluid, transfusion syphilis, and the use of the darkfield. By putting the personal touch and genuine consultant discussion into replies to query letters a very effective educational instrument can be made of them, and the cooperation between state and private practice greatly enhanced to the advantage of all types of patients. For details as to the mechanism involved in efficient service reference should be made to the above designated authors papers.

Possibilities and Limitations of Consultation.—The physician who seeks consultant direction in the management of a patient with syphilis should both expect and desire to have his patient completely reexamined by the specialist in accordance with a systematic schedule This arrangement is preferable to a fragmentary examination in which part has been covered by the physician and part by the specialist. The report made to the physician should give the complete examination results, the discussion of the meaning of the findings, and a clear-cut prescription for treatment procedure in which doses, time intervals, avoidance of complications reasonably to be expected and so forth, should be carefully detailed It is, however unreasonable for the referring physician to expect that such a prescription can cover a period much greater

than a year or that it can be extended indefinitely merely by subsequent correspondence or that an accurate description of the procedure to be followed can be made foolproof or impregnable against the defects of bad technic and unsatisfactory execution. As in the reduplication of scientific experiments in which it is part of the code to use the exact technic of the originator so in carrying through technical suggestions regarding the treatment of a patient, very slight departures from original instructions may have very serious significance. It is for this reason that the consultant prescription should take all reasonable account of difficulties that may be anticipated and instruct the physician who is to assume a direct responsibility in regard to all possible details. The physician should provide for himself a reasonable groundwork by reading accessible periodical and other literature.

Obstacles to Thoroughness in Treatment.—Rapidly achieved symptomatic results and the inconvenience of good methods constitute the two most serious bars to the thoroughgoing treatment of syphilis at the present day. A patient who fifty years ago lived with the outward evidence of his disease for weeks or months while a slow-acting regimen of mercury by mouth and the course of his infection gradually developed his natural resistance to the point where symptoms responded, is now relieved of all knowledge that he has syphilis within a few days. He can be held to an awareness of his condition only by the rather tenuous and unreal tie of a blood test, which, after a few repetitions he regards as a new-fangled device for "keeping him coming." Colonel Harrison has called attention (personal communication) to the bad effect on treatment continuity of informing the patient as to the outcome of his earlier blood tests in the course of treatment. The patient has learned by hearsay to regard the negative blood test as the goal for which he is striving and the moment he learns that it has arrived, he steps out of bounds and vanishes.

Among other serious obstacles to thoroughness are the effects of pain and reaction in discouraging the patient, and of failure on the part of the physician to make a sufficiently close contact with the patient in the first two or three interviews to gain his confidence and educate him to his responsibilities.

Discomfort, pain and reaction are the present-day barriers to the control of syphilis. Colonel Harrison's experience in the British Ministry of Health, for example, leads him to oppose the use of spinal puncture as part of the procedure of a public health clinic because reaction and loss of employment become to his mind, so serious that the ultimate purpose of the system of venereal disease control is lost sight of—the treatment of the patient to noninfectiousness. In a survey carried out by Pugh and associates in the clinic at the University of Pennsylvania, it was shown that discomfort, especially from intramuscular injection, was apparently responsible for the second largest proportion of lapses from treatment, being exceeded only by failure to tell the patient the facts of the disease with sufficient emphasis.

Referring to the vital importance of the first contact with the patient in insuring continuous and cooperative response, I know of nothing which is harder for us to do than to take the time needed to meet our responsibilities in this particular. Our students are compelled to memorize and recite the substance of the first interview with a syphilitic patient, for there indeed the future of the disease is more often determined than anywhere else. We have not found the spinal fluid examination to compare with either the factors previously mentioned or with a number of others as deterrents to continuance of treatment.

GENERAL THEORY OF MODERN TREATMENT: THE FUNCTIONS OF DRUGS

The Mechanism of Chemotherapeutic Effect.—Even so recently as 1926 (first edition of this text) it was possible with a fair degree of conformity to opinion to describe for practical purposes the mechanism of drug therapy in

syphilis in terms of four items specific *versus* nonspecific effect, and spirillicidal *versus* resistance-building action. Current developments which have compelled the rewriting of this section indicate that the mechanism of chemotherapeutic effect in syphilis is far too complicated to be included in such a relatively simple schema. None the less, the terminology previously employed has the merit of teaching value and can serve as a guide to clinical practice without too completely violating the canons of experimental and scientific accuracy

The Parasitotropic Views.—A number of investigations have shown that the mode of action of one therapeutic compound upon two different types of organisms, or even upon two species within the same family may vary considerably and that compounds within the same group, as for example, the arsphenamines, may act in different ways upon the same organism. With regard to the action of the arsenicals, two groups of thought are apparent the older of which the theories of Schumacher are representative considered the action of an arsenical to be spirochetotropic and mediated through the oxidation-reduction mechanism of the living organism. Muhlpfordt regarded the effect of the arsphenamines as that of powerful reducing agents, and was in doubt as to whether the spirochetotropic effect was exerted by way of chemical reduction or as an actual action of the arsenic. Voegtlin, Dyer and Leonard, among others, supported the conception that arsenoxide, a decomposition product of the arsphenamines, was instrumental in the parasitotropic and parasiticidal effect of these drugs and that this action was mediated through sulfhydryl compounds such as SH-glutathione. The action of the introduced arsenic is therefore that of interference with the oxidation mechanism of the cell. Schumacher's most recent statement draws upon the lipoprotein mechanism and contends that the rapid lysis of spirochetes following an arsphenamine is the result of the liberation of lipoproteolytic ferments. Schumacher contends that the arsphenamine base is lipoprotein soluble is liberated by the carbon dioxide of the blood and is a powerful reducing agent which destroys the spirochetes as soon as it is bound to them, thus acting through interference with their oxidation mechanism. Eagle has recently (1938–1939) investigated the mechanism of chemotherapeutic effect by a series of *in vitro* studies controlled by animal inoculations. He demonstrated that the trivalent arsenicals and soluble bismuth salts exert a direct spirocheticidal activity in concentrations approximating those found in the blood after therapeutic doses of the compounds studied. This direct action was suggested by previous studies (Bronfenbrenner and Noguchi (1918) Schamberg, Kolmer and Raiziss (1917) Akatsu (1917), Weiss and Wilson (Kolmer) (1926)) but denied by Levaditi who believed tissue substances were needed for *in vitro* activity of the arsenicals. The spirocheticidal action is increased by increasing temperatures and little affected by serum. It is markedly inhibited by tissue derivatives and almost completely stopped by sulfhydryl compounds added in excess. Arsenoxide and bismuth compounds act in spite of removal of molecular oxygen, while the spirocheticidal action of neoarsphenamine, highly active aerobically is negligible when tested anaerobically because its action depends on molecular oxygen to form arsenoxide. Kolmer and his coworkers (1939–1940) almost simultaneous with Eagle showed the high spirocheticidal action *in vitro* of various trivalent arsenicals but were unwilling, because of variable factors, to consider *in vitro* action to be used as a measure of therapeutic effectiveness.

The Tissue-stimulation Views.—The contrasting view is well presented by Tryb. He opposes Lesser Blaschko, and Kreibich in their belief that the action of the arsphenamines is spirochetotropic and radically different from that of mercury which influences the defence mechanism. Tryb points out the many reasons for believing that at least a large part of the action of an arsphenamine is not upon the *Spirochaeta pallida* as such, but upon the organs and tissues of the body His theory thus tends to bring closer the conception of the action of the heavy metals and that of the arsenicals. It explains moreover some effects of nonspirillicidal arsenicals on syphilis. Briefly stated, Tryb maintains that following the use of an arsphenamine in secondary syphilis, for example the macular eruption disappears, not because the spirochetes are destroyed by the drug, but the spirochetes disappear because the drug has stimulated the tissue to a spirochete-destructive reaction A good deal of support for this more or less nonspecific view of the action of the arsphenamines is found in the accumulated observations on the rôle of the reticulo-endothelial mechanism in bodily defence Most of the observations on which these theories of organotropism and defence reaction are based, cite the great disparity between the antiparasitic action of the drugs concerned *in vitro*, and that *in vivo*. Amounts of the drugs too small to kill the microorganisms in the test tube are highly efficient when injected into infected animals. The clue to a possible rôle of the reticulo-endothelial system arose from observations on the storage of arsenical

drugs in the body following injection, for there can be no question of the influence of the reticulo-endothelial structures in storing arsphenamine. In the experimental infection of the mouse with recurrent spirochetes or trypanosomes, Kritschewski and Meersohn, and Feldt and Schott have shown that depression of the reticulo-endothelium by block procedures and splenectomy interferes greatly with the chemotherapeutic efficacy of arsphenamine compounds. Kritschewski and his associates therefore maintain that quick initial storage and gradual subsequent release of the drug by the reticulo-endothelial system contribute largely to the effect of the arsphenamines, the favorable effect of storage having previously been demonstrated by Voegtlin and his associates. Feldt and Eisenmenger have opposed Kritschewski and Jungeblut conception that the arsphenamine is oxidised to an effective parasitotropic oxide. Spirochetes proved t be much more resistant than trypanosomes in the presence of arsphenamine and arsenoxide, which perhaps explains the discrepancy between these uthors results and Voegtlin views on the importance of arsenoxide in spirocheticidal and trypanocidal effect. Kolmer Schamberg and Brown found arsenoxide-containing arsphenamines t be more spirillicidal than trypanocidal. More recent studies (Muir and Becker 1931 and Pfeiffer and Tatum) have thrown no new light on the rôle of the reticulo-endothelial system in chemotherapy

In spite of the obvious difficulty of reconciling these conflicting views the clinically observable rapidity of action of the arsenicals in destroying spirochetes in the active lesions of syphilis justifies pigeon-holing them as essentially the most potent spirocheticidal agents in modern syphilotherapy whether the action is exerted directly on the organism or through a powerful organotropic influence on some structure or group of structures in the defence mechanism of the body or both.

Turning next to the action of mercury and, in fact, of all the heavy metals including bismuth it appears that an effect much more distinctly organotropic or cellulotropic takes place with these drugs although Eagle has shown a direct action on the spirochete for soluble bismuth at least. It has been shown that the concentration of mercury for example, in the blood stream at the height of therapeutic effect is far too low to act as a direct spirocheticide (Sidlick, 1938) All the heavy metals share the peculiarity of producing their characteristic reaction, as has been pointed out by Levaditi and coworkers for bismuth as the result of storage of extremely minute amounts of the metals in the body cell Goldzieher and Peck, studying this action of mercury and of sulpharsphenamine on the reticulo-endothelial system, reached the conclusion that these two drugs stimulated the phagocytic activity of Kupffer s cells and suggested that antibodies might likewise be liberated through this action It may therefore be contended with reasonable conformity to recent conceptions, that the action of a heavy metal and particularly of mercury is conspicuously upon the body cells and that they are therefore the resistance-stimulators par excellence in spite of a demonstrated *in vitro* spirillicidal action (Eagle, 1939 Sollmann and coworkers) In their therapeutic use they require reinforcement for spirillicidal effect from the much faster-acting and spirochete-destroying arsphenamines The intermediate position between mercury and the arsenicals occupied by bismuth will be more definitely pointed out in the ensuing chapter on the heavy metals

Specificity *versus* Nonspecificity —Specificity is the term applied to those features of the action of a drug which are distinctive for syphilis and not shared by its general action on disease processes All the drugs in common use in syphilis except iodide have both specific and nonspecific effects. The more searching the analysis however the harder it becomes definitely to say just where specificity ends and nonspecificity begins in a disease with so distinct a nonspecific defence mechanism as syphilis. All the drugs used in the treatment of syphilis produce some effects which are general in character and not

Fig 55.

A SCHEMATIC COMPARISON OF THE TRIVALENT ARSENICALS, BISMUTH AND MERCURY

	Arsenical	Bismuth	Mercury
1	The most effective spirillicide	Also spirillicide	Practically not directly spirillicidal.
2.	Uncertain, probably minor influence on defence	Influence on defence intermediate	Major influence on defence
3.	Rapidly heals infectious lesions.	Too slow for public health purposes.	Does not control infectious lesions.
4.	Chief preventer of infectious relapse if adequately used.	An adjunct only in this capacity	An adjunct inferior to bismuth.
5.	Hence the critically essential drug in early syphilis.	Never use exclusively in early syphilis.	Totally inadequate alone in early syphilis.
6.	Used inadequately provokes allergic response and precocious tertiarism.	Allergic by-effects suggested by flaring of infections and provocation of mild eruptions	No allergy-inducing action.
7	Acts rapidly in all phases of syphilis.	Acts fairly rapidly	Acts slowly
8.	Provokes focal and general flare-up (therapeutic shock)	No recognizable therapeutic shock in ordinary dosage	No focal or general flare-up.
9.	Induces therapeutic paradox and healing fibroses.	Little or no paradoxic effect though suspected in hepatic and cardiac syphilis.	No therapeutic paradox.
10.	Hence dangerous at the outset in late syphilis of vital structures.	Safe at the outset in latent and late syphilis, but use circumspectly for heart or liver	Safe as preliminary treatment in late syphilis of any type
11.	Toxic for heart and blood vessels.	Low toxicity for vascular structures.	Low vasculotoxicity except in high total dosage
12.	Toxic for liver and skin	Low toxicity for liver and skin.	Low toxicity but greater than bismuth.
13.	Gastro-intestinal toxicity annoying not serious	Little or no gastro-intestinal toxicity	Marked serious gastro-intestinal toxicity early and late
14	Toxicity for mouth insignificant	Toxicity for mouth moderate, rarely serious.	Toxicity for mouth marked, consistent, often serious
15	Low renal toxicity	Low renal toxicity	High renal toxicity
16.	Marked nonspecific effects	Nonspecific effects uncertain but not marked.	Least nonspecific effect of all
17	Marked stimulant and tonic action.	Tonic effect good, not striking.	Definitely depressant, anemia, weight loss, malaise
18	Therapeutic efficiency often variable	Therapeutic efficiency varies with vehicle and salt.	Most stable and trustworthy, least erratic.
19	Contraindicated in certain blood dyscrasias (aplastic anemia)	No special effects.	Contraindicated in nonspecific anemias.
20.	Suited mainly for intravenous use.	Intramuscular only safe effective route.	Variety of modes of administration.

dependent on the fact that the patient is infected with the *Spirochaeta pallida*. The gamut ranges all the way from mercury, which is the most specific for syphilis (i. e., has the least important general effect on disease processes other than syphilis) to iodide, which is but little specific for syphilis (i. e., has the most important and extended action on other conditions and the least distinctive effect on syphilis). In many important aspects of syphilological work, as, for instance in the performance of therapeutic tests, it is constantly necessary to bear in mind the specificity of the agent employed in the test in order to interpret properly the response.

Fig. 56.

COMPARISON OF SPECIFIC AND NONSPECIFIC ACTION OF MEDICATION FOR SYPHILIS

	Mercury.	Bismuth.	Arsenicals.	Iodides.
Specific effects.	Marked stimulation of cellular (tissue) resistance to *Spirochaeta pallida*. Slight direct destructive effect on *Spirochaeta pallida*.	Same as mercury but more direct effect on organism.	Marked direct destruction of *Spirochaeta pallida* by chemical combination with organism either through an oxidation reduction mechanism or lipoprotein. Slight [illegible] y stimulation of cellular resistance.	None.
Nonspecific effects.	Formation of agglutinins and lysins. Action upon other processes with an infectious basis such as nonspecific periostitis, uveitis, etc. Intestinal antisepsis. Depressant effects.	I [illegible] ea l g use in other d [illegible] are nonspecific effect of bi[illegible]m[illegible]th (p. 180)	Formation of agglutinins and lysins. Possible reticulo-endothelial stimulation. Action upon other infectious processes including tuberculosis, lymphomas, uveitis, mycoses, etc. All these effects more marked than with mercury or bismuth. Destruction of intestinal parasites. Tonic effects of arsenic.	R [illegible] l l g effect on granu[illegible] l m t tissue in general.

Figure 56 presents a schematic summary of specific and nonspecific action in the field of drug medication for syphilis. No mention is made of fever therapy with its large element of nonspecific effect and its debatable specificity. A résumé of this sort should be used only with due regard for the still existing uncertainty in our knowledge of the action of the drugs enumerated.

Spirillicidal effect, even though its modus operandi as between direct attack on the organism and stimulation of body cells to phagocytize and destroy organisms is still under dispute, is a very real phenomenon clinically and forms the basis for the selection and emphasis on the trivalent arsenicals particularly in controlling infectiousness and dealing with early syphilis. This effect is conventionally contrasted with the action of mercury, which, by the ordinary methods of administration, is only very slightly if at all directly

spirillicidal. There is a good deal of reason to believe, however, that the lack of spirillicidal effect in the heavy metals, particularly mercury, is due to the limitations on dosage set by their high toxicity for the animal body. Bismuth, whose toxicity is markedly less than that of mercury, exhibits in the dosages which are possible in treatment a strikingly higher spirillicidal effect, and a rapidly absorbed soluble mercurial salt (i. e., the succinimide) given at frequent intervals because of the absence of storage effect, to be discussed later, can be shown to have spirillicidal action almost comparable to that of the weaker arsphenamines. Be that as it may, the practical issue concerns the securing of these effects in treatment and in that field it must be conceded that the arsphenamines and arsenoxides have an overwhelming advantage in spirillicidal action, that bismuth stands next, and that mercury brings up the rear with iodide apparently entirely devoid of spirillicidal action as such.

Clinical Demonstration of the Comparative Spirillicidal Action of Arsphenamine and Mercury.—The practicing clinician who uses the darkfield can determine for himself the spirillicidal activity of the drug which he employs in a qualitative if not a quantitative way by the periodic reexamination of secretions from a spirochete-containing lesion every three or four hours or even daily after an injection of the drug in question. In this way it is also possible to detect worthless and ineffective arsphenamine preparations and variations in individual patients' response to the drug. It must not be forgotten that observed variations in such tests may be due to the ineffectiveness of the drug quite as much as failure to respond on the part of the defence mechanism of the host (see treatment-resistant syphilis, p. 140).

Lévy, in a study in which bismuth and the arsphenamines were compared with respect to spirillicidal efficiency, found that the arsphenamines were four to sixteen times as rapid in their spirillicidal action as was bismuth. The neoarsphenamine used in Lévy's series caused the disappearance of spirochetes from a surface lesion, even in subtherapeutic doses, such as 0.15 Gm., within twenty-four hours in 3 out of 5 patients. With an initial therapeutic dose of 0.3 Gm. the spirochetes in 50 per cent had disappeared within twenty-four hours, in 38 per cent within two days and in 12 per cent within three days of its administration. It appears that the arsphenamines vary in the rate of their effect as do all drugs used in treatment. Even a water-soluble bismuth preparation could not cause the disappearance of spirochetes within twenty-four hours, as in the majority of patients treated with neoarsphenamine. The minimum time required for water-soluble bismuth to act was four days in one and six days in 8 cases. Inasmuch as mercury is greatly inferior to bismuth as a spirillicide, the obvious superiority of even one of the weaker though widely used arsphenamines (neoarsphenamine) is beyond dispute.

Our experience in the evaluation of certain arsenical drugs suggests that the rate of disappearance of spirochetes from the lesions of early syphilis is variable, dependent on many factors: cooperation of the patient, sanchoomness of the examiner, type and condition of the apparatus, reactivity of the patient, and the quality of the drug. Thus, with the same lot of drug the spirochetes may disappear from the lesions of early syphilis in from less than twenty-four hours to more than five days after the administration of a single dose of drug. Size of dose, within the limits studied (0.3 to 0.6 Gm.) apparently has little effect, in our experience, on the rate of disappearance of the spirochetes. On the other hand, Leopold found the rate of disappearance of spirochetes from lesions in patients treated with arsphenamine to be proportionate to the dosage. This was confirmed by Katz, who noted that half the full dose of arsphenamine seemed to be as rapidly spirillicidal as the full dose.

Special Cases—Pentavalent Arsenicals.—Mention of tryparsamide, acetarsone (spirocid, stovarsol), and aldarsone, which are pentavalent arsenicals, should be inserted at this point for fuller discussion later. These drugs, especially tryparsamide and aldarsone, show a relative lack of spirocheticidal action, but have a powerful effect upon syphilis of the nervous system, especially paresis. While it would not be advisable and in fact is impossible to speak of tryparsamide as a spirillicidal arsenical in the sense appropriate to the clinical scheme thus far developed for making clear the action of these drugs, it is, of course, quite conceivable that tryparsamide to

increase following narcosis. Owing to toxic effects, he considered the method unproductive question of some interest in the later discussion of the simultaneous administration of arsenicals with fever therapy. Leonard has confirmed the finding of several other investigators as to the relative impenetrability of brain tissue to bismuth. It should be recalled that tryparsamide is not *spirillicidal to any significant degree. An interesting* by-product of this investigation was the migration of the introduced *Spirochaeta pallida* from the spinal canal to the testicles, in which sit primary lesions developed without local reaction in the nervous system.

In any event, it is apparent, either that the chemical properties of a tissue which make it incapable of combining with certain drugs or the impenetrability of the tissue or its membranes to drugs with differing electrochemical properties (i. e. colloids *versus* crystalloids) will play an important part in future investigations for singling out individual structures for specially effective treatment. Hanzlik and his coworkers (1935 1937 1938) for example, have utilized such considerations in developing a compound of bismuth iodobismitol which it was hoped would be especially effective in penetrating the nervous system. Their claims, however have not been confirmed by Klauder and Brown (1934) Sezary Barbé and Lackenbacher (1934) or by Levaditi and his coworkers (1933)

Drug Fastness and Treatment Resistant Syphilis.—The clinician has become so accustomed to the rapid disappearance of the early manifestation of syphilis under the modern antisyphilitic drugs that any delay is sure to excite concern. In spite of the fact that the concept of drug fastness or the failure of syphilitic lesions to respond normally to the antisyphilitic agents (arsenicals, bismuth salts and mercurials) antedates the clinical use of the modern antisyphilitic remedies, there is still no definite knowledge as to the mechanism and cause of this phenomenon. At the beginning of the arsphenamine era there were relatively few reported cases of treatment resistance. Since 1921 an increasing number of examples of treatment-resistance in syphilis has appeared in the European literature. No such increase has been noted in the United States. (Moore and Robinson 1930 Beerman 1936.)

Treatment-resistance may occur in any phase of syphilis. From the clinical standpoint treatment-resistance in early syphilis consists essentially of (1) persistence of lesions, (2) persistence of positive blood serological tests, and (3) persistence of spirochetes in lesions in spite of usually adequate treatment. Although serologic (reagin) fastness and serologic relapse during therapy are regarded by some as manifestations of treatment-refractory syphilis, the persistence of *Spirochaeta pallida* in the lesions is the most valid criterion of this state in human syphilis. Various grades of clinical resistance to treatment have been described ranging from instances of relative resistance through true resistance to a condition wherein treatment actually seems to stimulate the disease (arsenoactivation). The cutaneous lesions of treatment-resistant syphilis are often papulosquamous and psoriasiform and have a characteristic localization, being distributed as a rule on the face neck, penis and upper extremities. Many treatment-resistant patients react poorly to arsphenamine (Jeanner). Seronegative secondary syphilis ordinarily is rare (about 1 per cent) but in treatment-resistance syphilis the tendency to negative blood serological reactions occurs about five times as often. Moore and Kemp noted that the positive blood serologic reaction of a group of treatment-resistant patients tended to become negative very readily under treatment.

The *consensus* in the literature maintains that the cause of treatment resistant syphilis lies in one factor or in combinations of three factors the

peculiarities of the host, the potency of the drug and the peculiarities of the strain of *Spirochaeta pallida*

The host has been considered by many to play an important, if not the most important, rôle in the causation of treatment-resistant syphilis. Many arguments and observations have been adduced in support of this deduction. Some authors believe that the deprivations of the first world war may have been responsible for the increase of treatment-resistant syphilis in Germany. Others, however, note that treatment-resistant syphilis has increased in countries not affected by the first world war blockade. Some investigators think that the reaction to arsphenamine is influenced by such factors as race, climate, diet, habits, nervous strain, intercurrent disease and bodily constitution. (Moore and Robinson, 1930.) Another group holds that certain individuals lack the ability to change the inactive form of an arsphenamine, as administered, to the "avid" or potent form in the body (Miller 1931). Recently Netherton (1937) has suggested an ingenious method of testing this idea by observing whether or not arsenoxide, the "avid" form of arsphenamine, is effective against arsphenamine-resistant syphilis. Experimental testing of this idea is balked by the fact that Raiziss and Severac (1935) have found that the minimum curative dose of arsenoxide for rabbit syphilis is very nearly the maximum tolerated dose. In a clinical study, however, Beerman, Ingraham and Parner found in common with other observers (Beckh and Kulchar 1930) (Robinson 1937), (Dalton 1937), that syphilis may resist arsenoxide (mapharsen) treatment and that this drug behaves exactly as any other arsenical in regard to treatment-resistant syphilis. Netherton (1937) claimed that resistance to both arsenic and the heavy metals tended to incriminate the host as responsible for the condition. In addition, a number of vague but imposing theories involving the host have been advanced as possible explanations of treatment-resistant syphilis. They include such items as changes of the drug within the body into a form to which the parasite is immune (a variant of the metabolism theory noted above) and failure of the defensive powers of the host. The latter may be resident in certain cells or may result if all the tissues of the host become "immune" to the injected medicament. Several authors, most recently Netherton (1937) have argued that different responses to treatment in partners of conjugal syphilis means that with the same strain of *Spirochaeta pallida* under similar conditions the progress of treatment becomes a function of host variation. This argument would hold were it not for the fact that certain observers have seen conjugal syphilis evolve with remarkable synchronization. Finally a miscellaneous collection of proposals has been advocated with so little sustaining evidence that the limitations of space preclude their enumeration.

Changes and fluctuations in the manufacture of antisyphilitic arsenicals have caused the rôle of these drugs in production of treatment-resistant syphilis to be variously interpreted. No one has succeeded in establishing the drug as the basic factor in treatment-resistance, but some facts merit further consideration. For instance: the potency of arsenicals has been diminished by efforts to reduce reactions to them; the consequences of this change are highly debatable. Various manufacturers also have produced drugs of varied efficiency, the variations being caused either by ineffectiveness of a given formula, or by lack of uniformity in the processing of similar formulae. Even drugs of different lots, presumably made under identical conditions and by identical methods, display variable curative properties. Finally it is possible that an effective drug may induce treatment-resistance when it is used in subcurative doses; for example, the recent report by Beckh and Kulchar (1939) of eighteen cases of syphilis resistant to various arsenicals, including mapharsen, in which more cases occurred after combined (concurrent, simultaneous) than after an alternative plan of treatment, may have been due to chronic underdosage of each component to avoid reactions.

The part which *Spirochaeta pallida* may play in causing treatment-resistance has received much attention. Several authorities have suggested that this organism itself may be directly or indirectly responsible for ineffective treatment. Some have suggested that the spirochetes may be located where treatment is ineffectual, e. g. in the brain, or that varied phases in the life cycle determine different reactions to drugs. Indirect evidence of the possible rôle of *Spirochaeta pallida* consists largely of clinical observations which suggest treatment-resistant strains. Similarity in the course of some cases of conjugal syphilis suggests that strains may differ in their qualities. This argument, however, is no more convincing than that which is supposed to establish the host's causative rôle in treatment-resistance. Laboratory investigation, in our opinion, affords the most indubitable evidence of the importance of *Spirochaeta pallida* in the causation of treatment-resistance, and incidentally suggests the possible occurrence of drug-fast strains.

Evidence of the existence of drug-fast strains is based upon (1) studies of the effects of drugs upon spirochetes *in vitro*, (2) attempts to increase the tolerance of spirochetes to larger doses of drugs by subjecting infected animals to subtherapeutic doses; and, finally (3) attempts to rear in animals strains of spirochetes obtained from patients known to be resistant to treat-

ment Before presenting the data relative t these methods of laboratory study one must concede the basic possibility of the existence of strains of this organism ith individual biologic and elective localization characteristics. While evidence on this point is conflicting, there is slight balance in favor of the independent existence of strains in the biologic sense.

Akatsu and Noguchi in 1917 found that *Spirochaeta pallida* could be made five and half times more resistant t increasing doses of drugs by cultivating the organisms in media containing various arsenicals and mercuric chloride in concentrations just short of suppressing the growth completely Stjoskal and Fantl, studying the viability of *Spirochaeta pallida* in the hanging drop, concluded that arsphenamine kills spirochetes from mercury-treated patients much more slowly than it does those from untreated patients. Rubin and Szentkiralyi' studies did not, however confirm this observation that preliminary use of mercury increases the resistance t subsequent arsenical treatment. Study of the arsenic content of spirochetes may throw some light upon the question of the spirochetal factor in treatment-resistance. Feldt, in his study of the metal content of the spirochetes of relapsing fever after treatment of rats infected with an arsphenamine-fast strain, noted that arsphenamine-fast strains take up as much arsenic as normal strains, in con trast t trypanosomes in which resistant strains take up less arsenic tha normal strains. As yet no studies have ppeared on the comparative arsenic absorptive capacity of arsphenamine-fast and ordinary *Spirochaeta pallida*.

In 1910 Margulies studied the effect of subcurative doses of arsphenamine on trypanosomes in mice and on spirochetes, including *Spirochaeta pallida*, in rabbits. She found that the spirochetes, in contrast t the trypanosomes, failed t become accustomed to small doses of arsphenamine Nichols and Rothermundt and Dale likewise failed to demonstrat arsenic-fast properties of *Spirochaeta pallida* in experimental rabbit syphilis. Launoy and Levaditi (1912) were able to produce mercury fastness of *Spirochaeta pallida* in rabbits by the use of subcurative doses of mercury Frei, however was unable to confirm their findings. Gonder (1912) using subtherapeutic doses, produced the first artificial arsenical fastness of spirochetes in animal (*Spirochaeta gallinarum* and *Spirochaeta recurrentis*) He suggested such possibility for *Spirochaeta pallida*. Klauder (1924) by administration of subcurative doses of arsphenamine, as ble t develop strain of spirochetes in which the therapeutically effective dose of arsphenamine was raised 68.0 per cent, showing actual resistance of the infecting organism t the arsenical. These arsphenamine-resistant spirochetes ere normally sensitive to bismuth. Feldt has recently confirmed this ork. On the other hand, Greenbaum and Rule (1936) reported that they had used Klauder strain of *Spirochaeta pallida* and his technique during three years experimentation, but that repeated exposure to small doses of arsphenamine did not produce increased resistance. Sei and Giemsa were unable to produce bismuth fastness in *Spirochaeta pallida* by treating syphilitic rabbits with gradually increasing subtherapeutic doses of bismuth.

In summary w may say that few early experimental studies (Margulies, Nichols, Rothermundt and Dale Frei) seemed to indicate that treatment-resistance could not be induced experimentally by subtherapeutic doses of drugs. Other early studies and most recent ones, however suggest that resistance to drugs, or progression of the disease in spite of treatment, can be produced by experimentally exposing *Spirochaeta pallida* to inadequate doses. Recent extensive experience of the Cooperative Clinical Group also seems to show that small doses induce tr t ment-resistance. (Stokes, Usilton and coworkers, 1934)

Many investigators (Hoffmann and Armuzzi, Navarro-Martin, Jesner Nothaas, Bismosero, Zoon, Schoch and Stern, Schoch) have inoculated animals ith organisms from treatment resistant patients in ttempts to determine whether resistance depends upon altered biological properties of *Spirochaeta pallida*. All except Schoch (1937) and Beerman agree with Kolle observation, made in 1924, that strains of *Spirochaeta pallida* isolated from treatment-resistant human beings apparently were not treatment-resistant in rabbits. The investigations of those who feel that spirochetes from treatment-resistant patients lose their resistance in rabbits, how ever are open t several criticisms. In the first place, most of the studies were of short duration Furthermore, the criteria of treatment-resistance in rabbits used in most of these experiments (disappearance of spirochetes and lesions) are not reliable. A more significant index of sterilization is the popliteal lymph node transfer method of Brown and Pearce which was employed in the study of Beerman (1936, 1938) and Beerman and Severac (1942) Another possible cause of failure is that the organisms may lose their treatment-resistance when transferred from man t rabbit.

In 1932 Beerman obtained strain of *Spirochaeta pallida* from patient whose infection had been uninfluenced by total of 5.4 Gm. of various arsenicals. In summary study of this strain to date (1942) Beerman and Severac showed that over nine and half years 13 of 51 rabbits infected with this strain ere not cured by doses of potent arsphenamine ranging from slightly more to almost twice the curative dose for rabbit syphilis required by the Nichols-Hough strain

of *Spirochaeta pallida*. Chains of treatment refractoriness noted by Beerman and Severac suggested a possible explanation for the unpredictable way in which treatment-resistance affects one or both parties in conjugal syphilis presumably caused by the same strain of *Spirochaeta pallida*.

The prevention of treatment resistant syphilis depends largely upon adequate treatment of early syphilis This includes careful and frequent examination of the relapse sites abandonment of the old idea of abortive cure high initial dosage of the arsenical alternating treatment use of more effective preparations (arsphenamine in preference to neoarsphenamine) improvement in the health and hygiene of the patient.

Fully established treatment-resistance in syphilis may respond to (1) changing the preparation or drug used to another member of the same group e.g from neoarsphenamine to arsphenamine (606) (2) changing the manufacturer's brand of the same drug (3) changing to another type of antisyphilitic agent e g from arsenicals to bismuth salts mercurials or minor antisyphilitic drugs, especially gold Among nonspecific measures are included (1) high caloric diet (2) temporary suspension of antisyphilitic treatment (3) elimination of other intercurrent systemic diseases (4) shock therapy with milk, gonococcus vaccine, autohemotherapy sodium nucleinate fever induced by malaria or other methods

An excellent example of the parasitological criterion of persistence of spirochetes is furnished by the case reported by T H. Miller in which a three-day old primary lesion, darkfield positive and seronegative to Kolmer and Kahn tests continued to develop in size and the serological tests to become slightly and then strongly positive during a period of thirty-eight days in which the patient received 7 injections of arsphenamine (606) with the continued presence of *Spirochaeta pallida* in the primary lesion and the obtaining of a positive gland aspiration. The arsphenamine employed was from a reliable manufacturer was from two entirely different lots and was shown by subsequent investigation both by the manufacturer and the Public Health Service, to have a trypanocidal activity somewhat higher than that required by the Government standards. The primary lesion healed promptly and the serological tests became negative following two injections of sulpharsphenamine intramuscularly after which treatment was continued with bismuth and sulpharsphenamine The peculiarities of the host in this case were reinforced by a marked tendency to vascular reaction evidenced by repeated nitritoid crises, and the patient ultimately died suddenly of aleukemia hemorrhagica following a sulpharsphenamine injection. A inoculated rabbit unfortunately died and the strain was lost.

It is obvious that in interpreting the clinical phenomenon of drug resistance especially to arsphenamine, the therapeutic efficacy of the drug as such must be carefully proved. It seems not improbable that outbursts of arsenic-fastness in the syphilitic population of individual localities such as that of Lyons, as reported by Nicolas may be due to the therapeutic inefficiency of a widely distributed lot or brand of such a drug as neoarsphenamine which is known to fluctuate markedly in its therapeutic potency

Treatment Allergy —The arsphenamines have a distinctive and unfortunate peculiarity of great importance to the general management of treatment for syphilis This is the ability when insufficiently used particularly to induce a state of hypersusceptibility in the patient which results in fulminating relapse, provided the infection has not been extinguished The analogy of this peculiar state to the "umstimmung" or allergy of late syphilis is quite apparent clinically for the allergic type of relapse usually takes on the clinical characteristic of huge and destructive gumma formation in skin bones, or even the nervous system A convenient though by no means an evaluated theory of this sometimes disastrous result of insufficient treatment is the

view that the rapid destruction of the organisms of the disease by the arsphenamine group of drugs deprives the body of its one primordial and essential stimulus to fight the infection on its own account, namely the presence over a long period of time of the pathogenic agent. It is essential therefore, to impress both patient and physician especially in the case of an early infection with the understanding that curative treatment is something of an all-or-none affair If not followed through to a finish the patient is left both without cure and without defence. In the older mercurial days, he was left without cure but with some though an imperfect defence Correspondingly the physician who unwisely adheres to short arsphenamine courses unsupported by other methods of treatment is criticizable in that he has laid his patient open to the possibilities of treatment allergy The relation between treatment allergy and arsenic-fastness may be closer than would be imagined at first thought in that the persistent positive blood serologic reaction, for example may represent a phase of serological hypersusceptibility to a very small number of organisms of little practical importance to the future of the patient. Speculation aside however it cannot be too strongly emphasized that much of the blame that has been laid at the door of the arsphenamines for the induction of premature neurosyphilis resistant, destructive lesions, and inveterate relapse or serological fastness is the result of the *abuse* not the proper *use* of the drug. Too little arsphenamine especially in the early case, is at times more dangerous than too much or none at all (see Figs 423 and 434) It is always necessary to carry the drug to a more or less empirical maximum and essential, moreover for reasons presently to be considered, to reinforce its action with that of a heavy metal. Cases of malignant precocious tertiarism in spite of intensive arsphenamine therapy have been reported by Pinard Vernier and Vernini, Fruehl and others

NONSPECIFIC THERAPY IN SYPHILIS

General influences of a nonspecific character affecting the course and therefore the treatment of syphilis have been mentioned as follows influence of sunlight and thyroid activity in experimental animals influence of climate race, privation and of stress and strain just cited in connection with arsphenamine resistance the deleterious effects of focal and intercurrent infections trauma and other influences creating a *locus minoris resistentiae* protective effect of extensive involvement of the skin and osseous structures particularly both in experimental animals and in man effect of the general reaction of the disease in the secondary stage as a preventive of relapse.

An interesting recent therapeutic development, combining, in all probability the action of light, the stimulation of the skin to inflammatory reaction, and possible nonspecific protein effect is the combination of quartz lamp therapy and autohemotherapy (whole blood injections) recently reported on by Rajka and Radnai as particularly successful in the nonspecific treatment of tabes. W have personally employed ultraviolet light for some years in the relief of tabetic lightning pains.

Chemotherapeutic Effects with Nonspecific Phases—Nonspecific Uses of Mercury—While mercury is probably the most specific drug in its action in the entire group of antisyphilitic medicaments, its beneficial effects in lichen planus, nonspecific periostitis, in nonsyphilitic uveitis and chorioiditis, lupus vulgaris and even in epidemic influenza, are well known

Nonspecific Effects of Bismuth.—These are being increasingly discovered

Lupus erythematosus has been treated effectively with bismuth by Nicolas and his co-workers (1929) and MacKenna. We believe that the hydroxide is especially useful. We have also observed good effects in lichen planus (*cf* Grossman, 1932, Sonck, 1936)

Lurie 1932, showed that palmar and plantar verrucae respond to intramuscular injection of bismuth salicylate Shellow (1931) modified the treatment by using a soluble bismuth preparation locally (The response of verrucae to suggestion (Bloch) must be recalled in evaluation of any therapeutic procedure) Recently Schwartz (1939) suggested the use of bismuth injections to control the course of therapeutic malaria (Cole DeOreo, Driver Johnson and Schwartz, 1940) This observation was confirmed by Brunsting and Love (1940) and Young *et al.* (1943) Mais ld (1940) treated tonsillitis with bismuth and Saltzman (1942) found it effective in two cases of infectious mononucleosis. It is also useful in treating morphea. An interesting side action of bismuth is the possibility that latent plumbism may become active after the injection of it as an antisyphilitic agent (T Epstein, 1940).

Nonspecific Effects of the Arsphenamines.—A part of the striking and numerous nonspecific effects of the arsphenamines arise undoubtedly from the contained arsenic. Thus the tonic action of the arsphenamines as contrasted with the depressant influence of the mercurials if not a major is at least a most welcome addition to modern treatment regimens for syphilis.

The anemias and hospital pallors, falling weight curves and intractable anorexias are now part of the syphilological limbo of the almost-forgotten mercurial days. In fact the patient receiving an arsphenamine is today in more danger of seeming too well than too ill and thus easily discounts his plight and imagines himself the victim of a trivial ailment. The combined tonic and healing effects, the latter of course in part but not altogether specific of an arsphenamine give this group of drugs an unrivalled therapeutic "push" or curative power Where the older treatment slowly and laboriously educated reluctant body cells to defend themselves, the newer medication sweeps upon the field with a dash which for the first time in history seems to make almost visible the promise of actual extinction of all the organisms. Whether cure is possible or not, there is no mistaking the immense contribution in power and effectiveness brought into the syphilotherapeutic armament by the arsphenamines.

The extent and range of the action of the arsphenamines upon disease processes other than syphilis are strikingly indicated in Fig 57 which endeavors to catalogue under four grades of therapeutic utility the large number of conditions in which these drugs have been found useful The nonspecific aspects of the mechanism were presented on page 140 in connection with the modus operandi of the drugs

A part of the action in certain of the conditions enumerated arises from the stimulation of defence and the formation of agglutinins, lysins and antibodies of low specificity in part, perhaps, not only through action on the reticulo-endothelial system but through parasiticidal and bactericidal action in the intestines and the ill-defined tonic effect of arsenic. Nicolas, Gourmont, Gaté and Charlet showed that the administration of small doses of arsphenamine produced definite increase in agglutinins for tubercle bacilli in the blood of patients with tuberculosis. Toyama and Kolmer showed that large doses of either mercury or arsphenamine inhibited the formation of agglutinins and lysins, while small doses encouraged their formation. Tzanck and Pelsois, and Ravaut, in France, and Stokes in this country called attention to the clinical results which could be secured by treating tuberculids and tuberculous lymph nodes with the arsphenamines, effects sometimes quite as striking as those obtained in syphilis and a potentially fertile source of error in diagnosis. In conjunction with these observations, Benedict and Stokes have noted improvement in patients with inflammations of the uveal tract which could not be traced to syphilis, and Benedict and O'Leary published a report of results in a series of patients in most of whom syphilis had been quite definitely excluded The arsphenamines have also been successfully employed in some cases of blastomycosis (the late F G Harris rated it as almost specific in this condition), actinomycosis, and sporotrichosis, in multiple benign sarcoids, Hodgkin disease, lymphosarcoma, and mycosis fungoides in streptococcus septicemia; in Vincent's angina and erythema multiforme in intestinal infections with Lamblia and Entamoeba histolytica; in trichiniasis, malaria and pellagra and in multiple sclerosis in the absence of syphilis. Osgood and

his associates (1938–1942) demonstrated the superior effectiveness of neoarsphenamine over various members of the sulfonamide group by the ingenious device of the marrow culture technic hich permits controlled study of therapeutic agents against bacterial infections in the presence of human cells. By this method it was show that neoarsphenamine in concentration of three parts in a million was more effective against *Staphylococcu* *reu* or *Streptococcus viridans* than one t 10,000 concentration of either sulfanilamide or sulfapyridine nd did not significantly damage marrow cells. (1939–40)

Fig. 47

THERAPEUTIC USEFULNESS OF TRIVALENT ARSENICALS IN DISEASES OTHER THAN SYPHILIS

Distinctiv value	Acceptable	Occasional or variable	Debatable (isolated reports)
Bejel.	Amebiasis.	Actinomycosis.	Adenitis.
Pinta.	Arthritis (chronic)	Anemia pernicious (nonsyphilitic)	Agranulocytic angina.
Pneumonia (complicating syphilis)	Blastomycosis.	Anthrax.	Erysipelas.
Pulmonary spirochetosis.	Chorioiditis.	Aphthous stomatitis.	Leprosy
Rat-b t fever	Erythema multiforme.	Echinococcus infection	Liche planus.
Relapsing fever	Erythema nodosum	Glanders.	Lymph g loma venereum.
Rocky mountain spotted fever	Lamblia infections.	Gonorrhea.	Typhoid fever
Septic scarlet fever	Lupu erythematosus	Herpes zoster	Undulant fever
Y	Multiple sclerosis	Hodgkin disease	V ricella.
	Tuberculosis.	Leukemia.	Yellow fever
	Adenitis.	Lymphosarcoma	
	Lupus vulgaris.	Malaria, black water fever	
	Erythema induratum.	Mycosis fungoides	
	Sarcoid.	Pellagra.	
	Synovitis.	Pemphigus.	
	Tuberculid.	Periadenitis mucosa.	
	Uveitis.	Periostitis (nonspecific)	
	Vincent angina	Puerperal fever	
		Pyelitis	
		Septicemia (streptococcal)	
		Trichiniasis.	
		Verruca plana.	

Of these varied uses, the application of treatment for syphilis in tuberculids, tuberculosis n the sarcoids, n nonspecific periostitis and osteitis in amebiasis and mycoses and in multiple sclerosis in the absence of syphilis, has led to confusion with syphilis. This point will be reemphasized in the discussion of the technic of therapeutic tests. The investigation for syphilis in all cases in which an arsphenamine is to be used for nonspecific action, should be thorough and yield negative results before treatment is instituted

Nicolas and his collaborators showed that the response to arsphenamine in tuberculosis depended to a considerable extent on whether the patient was showing a good resi tance and was on the upgrade or whether he wa on the

decline If the latter the tuberculosis was more likely to be unfavorably than favorably affected thus we have found to hold true in general for the utilization of nonspecific effects whenever they depend on stimulation of a resistance

Fig 59.—A papulonecrotic tuberculid with ulcerative lesions of erythema induratum and scarring (right leg) suggestive of syphilid There were numerous papulonecrotic lesions, and the history was typical. Full and repeated study for syphilis was negative. The linear scarring of the left leg represents the effort of a surgeon to remove the lesions as varicose ulcers. The patient was later sued for divorce on the ground that because her lesions had cleared up temporarily under arsphenamine she must have syphilitic infection.

Fig. 60.—Sporotrichosis of the thigh (cultural identification) healed by arsphenamine and mercury succinimide without iodides or roentgen-ray

mechanism The best results cannot be expected from patients who are on the downgrade. Where a merely antiparasitic action is invoked as in intestinal parasitism, this consideration is not important.

Uncertainties of Nonspecific Effect.—The securing of nonspecific effect is not a matter of absolute uniformity and it is difficult to analyze the effect of the procedure into its components.

Fig. 60.—Sarcoid infiltration of the face of the subcutaneous or Darier Roussy type.

Fig. 61.—Effect of [illegible] arsphenamine injections on the Darier Roussy sarcoid shown in Fig. 60. Note the large amount necessary to produce this result.

Fig. 62.—Effect of 15 arsphenamine injections on the sarcoid shown in Fig. 60.

In tuberculids the action is fairly constant and improvement takes place at a uniform rate, suggesting the action of treatment in syphilis, though somewhat slower. In tuberculous processes in the glands, throat and skin in the order named, there is less assurance of good effect. In mul-

tiple fibrosis, periostitis and osteitis the effect is secured occasionally but not frequently. In uveitis the results secured depend upon the age of the process, being very good in early acute cases and relatively poor in patients who exhibit old opacities, deposits and scars. The healing of tuberculids and erythema induratum (Chapter XV) is accomplished in from six to eight weeks and in more than 50 per cent is apparently permanent even in this notoriously relapsing condition. Tuberculous glands are occasionally spectacular in response. Sarcoids may require treatment for two or three courses before much effect is apparent, the action probably being due to arsenic which is known to influence these lesions favorably. Flare-ups or therapeutic shocks in tuberculous processes and uveitis occur and may create an even more confusing impression of syphilis. Patients with uveitis should be warned that they may have a flare-up, or they may become alarmed by a temporary decline in vision. The ultimate effect is usually good. If the process is very acute a two-week mercury succinimide preparation is desirable. The repetition of courses in nonspecific therapy does not follow the time-rules of syphilis. Tuberculids usually recur in spring and fall and for this reason and because there seems to be some advantage from a high total arsenic intake three or even four courses are sometimes desirable. Even though patients do not completely escape a recurrence the attacks are much milder and usually free from the constitutional accompaniments of arthralgia, tenosynovitis and anemia that are common in patients who have tuberculids. In other types of cases two courses may be given and further treatment made to depend on symptomatic indications. Focal infections should be removed, if accessible, but their removal is not essential to the securing of a good, though less permanent, therapeutic effect.

NONSPECIFIC PROTEIN AND FEVER THERAPY

The influence of intercurrent febrile infections in causing the involution or amelioration of other primary conditions has long been known. Finger

Fig 63.

CLASSIFICATION OF METHODS OF NONSPECIFIC (FEVER) THERAPY

Physical.	Chemical.	Nonbacterial protein.	Bacterial protein.	Active infection induction.
Diathermy High frequency oscillation. Hot baths. Heated air 1 luminous heat cabinet. 2. air conditioned cabinet (hypertherm) Blankets 1 plain. 2. electrically heated.	Sulfur in oil intramuscularly	Whole milk. Aolan (casein, etc.) Lipoprotein or gan extracts. Yeast extracts.	Typhoid paratyphoid vaccine Typhoid divided dose with H antigen (flagellar) Triple typhoid vaccine by continuous intravenous infusion (?) Pyrifer Coley serum Tuberculin.	Malaria. 1 tertian. 2. quartan. 3. spp. Recurrent fever Rat-bite fever

Lang, and others observed it in connection with various aspects of syphilis and Neumann reported the involution of a macular syphilid under the influence of an intercurrent pneumonia. Buschke and Freymann early observed that febrile arsphenamine eruptions associated with treatment had a particularly beneficial effect on the subsequent course of the syphilitic infection. The spectacular change in the prognosis of general paresis brought about by Wagner von Jauregg's introduction of malarial therapy has probably been chiefly instrumental in focusing attention, heretofore directed for more than

a decade upon chemotherapy upon the new possibilities and problems of nonspecific stimulation of the defence mechanism in syphilis "Stimulation therapy" as Schumacher calls it, can be accompli hed by a variety of methods which are classified in Fig 63

Regardless of the agent employed the first point for the practitioner to appreciate in his employment of nonspecific treatment in syphilis is the one limitation inseparable from the method. It is not appropriate to any treatment regimen which requires the rapid destruction of the *Spirochaeta pallida* In

Fig. 61

THE PHYSIOLOGIC EFFECTS OF NONSPECIFIC PROTEIN AND FEVER THERAPY
(A Summary Based on Nonnenbruch, Miller Jaffe, Krusen and Elkins, Solomon and Kopp, Simpson and Others)

1 A cellular rather than humoral therapy
2. Colloidal "shake-up" changes in tissue structure
3 Local inflammatory reaction aroused t disease sit
4 Products of increased cell break-down ppear in the blood
( ) adrenalin-like substances, (b) digitalis-like substances ( ) substances affecting the theoretical "heat-center —Freund.
5. W ter balance changes.
6. Blood changes acidosis followed by alkalosis sodium chloride prevents loss of base nd chloride (Danielson nd Stecher 1935)
7 Vascular permeability altered. Shock syndrome (Kopp and Solomon, 1937)
8. Increase in proteolytic nd lipoproteolytic enzymes (Jobling and Peterson, Schumacher)
9 Leukopenia followed by leukocytosis (macrophagocytosis) (Doa and Hargraves, 1936 1938)
10 Stimulation and hyperplasia of the reticulo-endothelial system (macrophagocytosis, etc.)
11 Increased nitrogen output.
12. Mineral metabolism influenced. Loss of sodium chloride
13. Anaphylactic shock effects.
14 Desensitization against proteins. Rise in resistance in general (Rusznyak and Koranyi) Inhibition of classical anaphylaxis in the guinea-pig (DeKruif and Simpson, 1940)
15 Antibody formation nd mobilization associated with, and increased by rise in temperature
16 Effects on sympathetic nervous system (blood pressure, increase in pulse rate, increase in pulse pressure increase in blood flow decrease in blood volume (G bson and Kopp, 1936 S. L. Osborne, 1941) rise in metabolic rate, deeper respiration ith little effect on rat inability of postural vasomotor reflex to react normally (Kopp, 1935–1939)
17 At fever levels the tolerated dose of an arsenical decreases (Mapharsen in experimental animals), but the therapeutic effectiveness of the drug increases far more rapidly (Carpenter and Warren)
18. Destruction of micro-organisms b body temperatures equalling their thermal death point.

THE *MODUS OPERANDI* REMAINS UNEXPLAINED

spite of experimental data strongly indicating that high body temperatures are spirochetacidal (Carpenter Boak and associates, 1930–1942, Bessemans and associates, 1929–1933) or that high temperatures increase the effectiveness of an injected drug (mapharsen) clinical experience shows that short periods of fever or a single prolonged fever are inadequate for the treatment of early syphilis. (Epstein and Cohen, 1935 Neumann, Lawless and Osborne 1936, Simpson and Kendell 1937 Simpson, Kendell, Rose 1942, Boak, Carpenter and associates, 1934 1942) Hence it should not be used without adjunct chemotherapy in the treatment of early infectious syphilis, a principle which

even the most enthusiastic malarial therapists such as Kyrle for example have not felt willing to set aside. Nonspecific therapy will unquestionably achieve by one or another means, combined with chemotherapy for example Kyrle (1924) Simpson, Kendell and Rose (1942) Boak, Carpenter and Warren (1942) a routine place in the treatment both of early resistant and late syphilis, but certainly in the present state of knowledge a vigorous warning which can be easily reinforced by a study of the literature should be given against any attempt to substitute nonspecific therapy for the use of powerful spirillicidal drugs, such as the arsphenamines, in the public health control of the disease

The *Modus Operandi* of Nonspecific Therapy —Some of the differences in viewpoint and method which beset present-day practice and theory in nonspecific therapy are we believe due to a lack of appreciation of the extraordinary range of action involved in this form of treatment. In order to illustrate the extreme complexity of the problem and the impossibility of admitting any one mode of action to be the sole effective one we have drawn up Fig 64 based upon the admirable recent summaries of Nonnenbruch, Miller Jaffe Krusen and Elkins Solomon and Kopp Simpson and others From this table it will appear that here are at least eighteen different processes going forward at practically one and the same time in the patient who is receiving any one of the various forms of nonspecific protein or "fever therapy

The chief effective modes of action re in all probability the stimulation and hyperplasia of the reticulo-endothelial system which follows all bacterial and foreign-protein invasion; the increase in proteolytic and lipoproteolytic enzymes, the latter emphasized by Schumacher as the principal feature of the nonspecific defence against syphilis, antibody formation and mobilization associated with, and increased by the rise in temperature; and the local inflammatory reaction aroused t disease sites by these forms of treatment The function of the anaphylactic mechanism, of the metabolic changes, of the leukopenia followed by leukocytosis and of colloidal shake-up of the body cells is all uncertainly defined It is not ithout reason, therefore, that Nonnenbruch concludes his summary by saying that the *modus operandi* in nonspecific therapy remains unexplained. The wide range of theories is well illustrated by the discussions of Gerstmann and of Peruts. Schumacher has repeatedly stressed the lipoproteolytic mechanism and has built up an elaborat and very plausible theory round this particular element, supporting it by such observations as those of Levaditi on the increased effect of bismuth in lipoprotein suspension and similar effects claimed for the arsphenamines (yeast protein injection) The large share taken by the reticulo-endothelial mechanism is summarized by Jaff in its general pplication. Histologic studies show that foreign proteins are productive of swelling, proliferation, basophilic staining and vacuole formation within the Kupffer cells. Macrophagocytosis by reticulo-endothelial cells certainly far outranks ordinary leukocytic phagocytosis in the control of many infections, and this is probably especially true of syphilis. The claimed superiority of the introduction of living infectious agent, such as the malarial parasite, in bringing about these changes in the reticulo-endothelial defences is the basis of the inference that spirochetes incidentally present are probably phagocytised in the same manner though this can hardly be said as yet to have been demonstrated. The only direct studies of resistance to spirochetes thus far recorded are those of Pentschew of Levaditi and of Deutz, in which it appears that the *Spirochaeta gallinarum* injected into the blood of young rabbits or mice, ppears for short time nd then disappears, unless the reticulo-endothelium system has been blocked, in which case the spirochetosis of the blood of the mouse is markedly increased.

The instrumentality of rise of temperature of the body tissues as such in the destruction of the *Spirochaeta pallida* has recently been emphasized by Schamberg and Rule who observed that rabbits could be protected from syphilis after intratesticular inoculation of *Spirochaeta pallida* if they received eleven consecutive daily hot baths under certain conditions which would produce an average rise of temperature of 4 F Believing that the thermal death point of the *Spirochaeta pallida* could be reached within the limits of temperature endurance of the host, they subjected rabbits t series of hot baths and found that the primary lesion healed almost with the rapidity of arsphenamine therapy and more quickly than after injections of bismuth. The

organisms disappeared in less than eight days and the testicles were entirely normal in seventeen days. The organisms were still present after forty-eight hours so that even under the favorable conditions of animal experiment the method does not equal the use of good arsphenamine or mapharsen in the rate of spirochete destruction.

The importance of adequate temperature rises and their relation to the thermal death point of *Spirochaeta pallida* is most effectively discussed in terms of the latest investigation in Simpson, Kendell and Rose review of artificial fever combined with chemotherapy in Supplement 16, Venereal Disease Information. Bessemans and his associates found that the application of heat to the testicular syphilomas of rabbits, regardless of the method used, destroyed *Spirochaeta pallida* when the temperature in the syphilitic lesion (as measured by small thermocouples) was maintained for one hour at 106° Fahrenheit (42° Centigrade) or for two hours at 104 Fahrenheit (40° Centigrade). Bessemans also found that *Spirochaeta pallida* in the popliteal nodes of the syphilitic rabbit rarely lose their virulence if the rabbit is subjected to sufficiently high body temperature only to destroy the spirochetes in the external lesions. It sometimes required a temperature of 114.8° Fahrenheit (46° Centigrade) for one hour to achieve the same results. On the other hand Carpenter and coworkers found that a body temperature of 106.7-107.6 Fahrenheit (41.5-42 Centigrade) maintained for six hours was uniformly sufficient to destroy *Spirochaeta pallida* both in the testicles and in the popliteal lymph nodes of syphilitic rabbits. This has been confirmed by Simpson and coworkers. Thus the in vivo thermal death time of *Spirochaeta pallida* will vary both with the height and the duration of temperature. The subsequent work of Bessemans, interrupted by the invasion of Belgium, and the now more complete experimental studies of Boak, Carpenter and Warren, appear to have clearly indicated that subcurative doses of an effective arsenical, combined with a subcurative elevation of body temperature give superior results in the treatment of experimental syphilis to the administration of larger amounts of drugs or higher temperatures alone.

Nonspecific Therapy in Early and Latent Syphilis.—Applying other methods than the induction of infection to the use of nonspecific therapy in early syphilis, Greenbaum and Wright showed that 4 per cent suspension of milk protein produced the involution of a certain proportion of secondary lesions and later that milk injections used in conjunction with neoarsphenamine were more effective in reversing the blood Wassermann reaction than neoarsphenamine used alone. They emphasize however that where any effort is made to apply such nonspecific therapy combinations to the treatment of early syphilis, the spirillicidal drugs should be used first because of the necessity for a rapid reduction of organisms. The distinction of having thoroughly studied the possibilities of malarial therapy in the treatment of early syphilis belongs to the late Kyrle who, by a large series of cases whose evaluation was interrupted by his death, succeeded in showing that in the early stages at least the treatment had not proved itself but that malarial courses, when administered between courses of the arsphenamines, produced a marked beneficial effect on the general course of the infection. Von Berde pointed out that while the primary lesion healed after the malarial siege, the adenitis and eruption subsequently developed, so that the method should be strictly interdicted in the treatment of seronegative primary syphilis (*vide supra*). Once the secondary eruption had, however, developed, the response was much more satisfactory. Instances were observed in which the malarial therapy gave rise to an induced allergic type of reaction, making the infection worse and leading to severe and destructive lesions. The use of fever induced by typhoid vaccine, in combination with chemotherapy has greatly impressed us as a method of dealing with resistant recurrences in late syphilis—particularly nodular infiltrative cutaneous lesions and bone lesions. The weekly induction of a bout of fever (two to four hours above 104° F.) with an injection of a moderate dose of any one of the standard arsenicals (by weight) causes involution of lesions previously resistant to arsenical and combined heavy metal therapy. Relapses may occur after a single or even two eight-treatment courses, but persistence has thus far yielded satisfactory results.

The combination of alternating courses of fever therapy and chemotherapy or the initiation of treatment with fever therapy particularly malaria in the case of interstitial keratitis as a complication of congenital syphilis, has now become established in this country at least, as standard procedure following the recommendations of Klauder and coworkers, representing the Cooperative Clinical Group. Practically the same statement may be made of the obstinate and destructive syphilomas of bone encountered in congenital syphilis, and of course of congenital syphilitic lesions of the nervous system, especially paresis.

Evidence is rapidly accumulating to indicate that combined fever and chemotherapy when facilities and experience for their proper use are available is one of the most effective methods of attack upon any phase of a syphilitic infection in which positive contraindications do not exist. The steady improvement in physical methods of inducing fever their simplification, and the apparently increased effectiveness of the arsenicals without corresponding increase in toxicity

have outdated the argument as t the advisability of the routine induction of malaria as part of the treatment of early syphilis. Other less objectionable method are rapidly becoming vailable. Kyrle and his successor Kerl, and Zieler while in the main proponent of the use of malaria in many phases of the treatment of syphilis, have influenced opinion more and more towards the extensive but not necessarily routine use of fever in the general treatment of syphilis. Zieler in summarizing the literature defined the limitations of effectiveness in certain specific states and syphilitic involvements, and insisted on thorough-going nd vigorous treatment with the arsenicals and heavy metals.

Combined Fever and Chemotherapy in Early Syphilis.—This subject will be more specifically reviewed under the treatment of early syphilis, but the most extended experience to date—that of Simpson Kendell and Rose (*loc cit.*)—summarizes the principles. In control series since 1032 these authors believe they have shown that fever alone or chemotherapy alone (the latter however not conforming to the full standard system for the chemotherapeutic treatment of early syphilis) was insufficient to produce satisfactory results. A combination of the two however in seventy-seven patients, of whom sixty have been quite carefully followed, indicates that in seronegative primary cases, the serologic reactions never become positive. Involution of lesions and disappearance of spirochetes progress at a normal rate. In seropositive primary syphilis, 02 per cent achieved satisfactory results in a single course of combined treatment which included a total of fifty hours with fever at an average temperature of 105.8° F (ten weekly sessions of five hours each) and later shorter courses aggregating thirty-six hours at the same fever were combined with chemotherapy which while not exactly defined apparently approximated thirty concurrent injections of arsenical and bismuth compounds. The two relapsing cases in this series achieved serologic negativity following a second course of fever-chemotherapy Two out of twenty patients with secondary manifestations in the first year of the disease (10 per cent) failed to achieve serologic negativity in eight cases of later and more resistant types the responses were less satisfactory and repeated courses more often necessary One of the interesting effects of this type of treatment was apparently the absence of exfoliative skin reaction which can conceivably be interpreted as an evidence of the antiallergic or desensitizing effect of the fever phase of the treatment. The combination of intensified short-term chemotherapy with fever is in process of trial by these workers and others (Thomas and Wexler 1941, Kaplan, 1042)

Physical Methods.—The trend in the use of physical methods of induction of fever in the treatment of syphilis has been first towards an increasing demonstration of the importance of the maintenance of high temperature for relatively long periods—and second the importance and feasibility of a steady simplification of technic. It is now apparent that the electrical methods of inducing fever by the oscillating current and by diathermy are unnecessary have no distinctive merit, and do have some dangers, including particularly the induction of electrical burns. The results in temperature rise at least, can be duplicated and improved on by the conditioned air cabinet (hypertherm of Kettering) and range downward through the use of cabinets and cradles with luminous bulbs to electrically heated blankets and finally to blankets heated by hot water bags and to the ultimate simplification of blankets alone with or without hot drinks. The bath technic of inducing fever has undergone particularly interesting and perhaps significant simplification by its application to the treatment of gonorrhea (Warren) in which

the patient is laid in an empty bathtub into which water is allowed to flow at a temperature ranging between 105 and 111 F When the water reaches the outlet level and the patient begins to feel the exhaustive and giddy symptoms which come on from dehydration and loss of chloride, he opens the outlet device, lets the water out, is dried retires to his bed on the ward and when his temperature under light covering is down to normal again he is ready to go about his ordinary business Apparently this type of fever jolt is capable of greatly increasing the effectiveness of the sulfonamides and its application to the treatment of syphilis may prove of much importance Dennie, Polsky and Lemoine (1930) reported good responses in late resistant and congenital syphilis by a similar technic. The more elaborate types of equipment, including the conditioned air cabinet, make perhaps, more provision for the comfort of the patient, but they require a highly specialized set-up and attendants whose skill must be proportional to the length of time that the patient's temperature is to be elevated. The self-recording rectal thermometer is probably as important as the body heating device itself since it makes possible accurate control of the temperature throughout the fever siege The patient escapes the discomfort and sense of prostration associated with foreign protein therapy It is important to maintain fluid and chloride levels and to watch for and avoid heat shock and prostration In the wider application of fever to the control of a disease like syphilis, simplification and elimination of complicated methods requiring treatment centers and special technical experience is the direction of progress.

Comparative Efficacy of Various Methods.—It is evident that too little is as yet known of the modus operandi of fever therapy to permit adequate comparison of the effectiveness of the various types of procedure. Much animal experimental work remains to be done and many years of evaluation of the long range effect of treatment for syphilis of which fever has formed a part. The impression is strong, with the authors at least, that malaria in late neurosyphilis and perhaps in congenital syphilis, and the physical methods in early and latent syphilis are, for a variety of reasons the preferred types of treatment today That such a statement today will necessarily hold tomorrow is too much to expect. The specific contributions of the Cooperative Clinical Group to the evaluation of this question in the treatment of neurosyphilis are summarized in Chapter XX

DOSAGE THEORY AND PRACTICE

The tendency to fall back on rules of thumb and a dosage scale in the treatment of syphilis is, of course inescapable and not to be too severely condemned. It is however necessary for one who would treat all aspects of the disease with discrimination to keep in mind a series of quasi-empirical maxims summarized briefly in Fig 65 which serve as a guide to the appropriate dosage for a given situation As regards the spirillicidal drugs especially one would imagine that the larger the dose and the higher the concentration of the medicaments brought into contact with the organism, the better the effect. Early studies of neoarsphenamine (Katz) suggested that this was not necessarily true, for half the full dose seemed to act as rapidly as the full dose In the production of non-specific effect whose importance in treatment as has been already stated seems to be on the increase rather than the reverse Toyama and Kolmer have shown that large doses of either arsphenamine r

mercury directly interfere with the nonspecific defence and diminish the production of agglutinins and lysins with which among other devices the body carries on its own fight against the invader Any considerable experience with the treatment by arsphenamine and mercury of other diseases besides syphilis confirms this experimental study by many clinical impressions. Large doses of arsphenamine have perhaps more prolonged spirillicidal effect, but the stimulation of general resistance seems to be lost when more than moderate dosage is employed The abuse of mercury by heroic dosage may also undermine the patient so rapidly that its good effects on the disease are lost in a general breakdown of resistance Thus far the tolerance to bismuth and the ability to stand large doses of it over long periods of time seem to surpass those of other antisyphilitic drugs.

Time-Dosage Relationships.—Experience with intensive methods for the treatment of early syphilis in animals, awaiting confirmation in man, has convinced Eagle and Hogan (1942) that within broad limits the curative dose of mapharsen with any one type of treatment is largely independent of the time period over which the treatment is given Their data suggest that repeated doses at short intervals are more effective than either one large dose or repeated doses at weekly intervals The total curative dose of mapharsen in rabbits was found within broad limits to be approximately constant, and since the total tolerated dose on any schedule of injections increases directly with the duration of treatment, they concluded that the margin of safety between the toxic and the therapeutic dose "chemotherapeutic index," may be increased continuously by prolonging the duration of treatment. An intensive treatment schedule as effective as twenty to thirty weekly injections of 60 mg (1 mg per kg) mapharsen and providing a comparable margin of safety would be at least approximated by (*a*) injections of 20 mg. mapharsen (0.3 mg. per kg) repeated twice daily for four to eight weeks (*b*) daily injections of 30 mg mapharsen (0 5 mg per kg.) continued for five to ten weeks or (*c*) injections of 60 mg mapharsen (1 mg per kg) repeated three times weekly for five to ten weeks The application of this theory to treatment for early syphilis is discussed in Chapter XIV

Prolongation vs Mass.—The Cooperative Clinical Group studies of the treatment of early syphilis apparently demonstrated a principle which it is important to bear in mind at a time when pressure is strong for the shortening and so-called intensification of treatment systems for early syphilis. From the CCG material (1932) it appears that the good results obtained by prolonging continuous treatment, for example for more than a year are more than double those obtained by continuous treatment for one year or less. Even irregular treatment gives three times as good results when applied for more than a year as it does when applied for less than a year Other criteria of favorable treatment effects bear out this relationship which may of course be due to the fact that prolongation of treatment is simultaneously an increase in mass, and brings about a closer and closer approximation to Eagle and Hogan's conception of the total curative dose at least of the arsenical. This has been estimated by Eagle and Hogan on the basis of their experimental work with rabbits as 1200 to 1800 mg of Mapharsen dosage determined by weight on the basis of 20 to 30 mg per kilo

Relative Effectiveness of Low vs High Dosage—While the question is complicated by differences in the therapeutic activity of various arsenicals and heavy metals and of individual lots of the same drug, it appeared from

the work of the Cooperative Clinical Group (Stokes, Usilton and coworkers, 1934) that there is definite evidence of the greater effectiveness of larger over smaller dosage scales In this study small dosage is rated as 0 2 to 0 45 Gm arsphenamine (606) and large dosage as 0 45 and over for men (0.3 Gm or over for women) The study indicated that large dosage does not cause any type of unfavorable outcome and that the smaller scale of dosage has definite shortcomings 7 6 per cent relapse or serologic fastness on the lower scale vs. none on the larger scale Nearly three times as much neurosyphilis develops on the lower dosage scale as on the higher dosage scale. Accordingly one of the genuine advantages of the intensified treatment systems will be their

Fig 65

SOME DOSAGE MAXIMS IN SYPHILOTHERAPY

1 Mak th first dose half or less than the prescribed maximum.
2. Follow this rule to avoid Herxheimer effect in ordinary cases when using shock-inducing drugs be doubl cautious if heart, nervous system, or special sense mechanism i involved.
3. Be even more conserv tiv if therapeutic paradox may develop.
4 Tak age, and weight into account. Sex as such is being increasingly disregarded
5. Learn schedule for children (see p. 275)
6. Persistence in underdosag (subtherapeutic doses) after the first treatment may activate and stir up or render refractory the early or latent case
7 Abrupt overdosag may sensitize or destroy tolerance (render patient reactive)
8 Long-continued overdosage produces accumulation, chronic intoxication, and injury t the eliminative mechanism
I drugs ith cumulative action, the larger doses and shorter intervals if used should be near the beginning (after the first) rather than toward the end of treatment season.
9 Use smaller dose when ( ) using short intervals; (b) seeking nonspecific effect ( ) treating the cachectic and the aged (d) in febrile states and intercurrent infections ( ) pregnancy (f) in organic disease (g) for tonic ction in lat infections (h) in serious visceral nd vascular impairment from syphilis ( ) when combining t o or more toxic drugs (including so-called combined treatment") in treatment (j) in the know hypersensitive or idiosyncratic patient.
10 Small dose courses should be long and repeated, and in the case of arsphenamines particularly demand heavy metal reinforcement t prevent activation nd relapse
11 Use larger doses when (a) using longer intervals, (b) seeking curative effects i early syphilis ( ) using the drug alone (d) treating the robust and fully developed individual.
12 In purely nonspecific therapy se moderat doses and longer intervals. Never base tolerance.
13 Th rate of accumulation and elimination and the routes for each drug used should be understood factors in determining dosage technic

a urance that the patient receives once and for all and early in the course of his disease the maximum dose that his weight will tolerate, and not any compromise with it dictated by a l w dosage scale or a lack of persistence in treatment.

Subtherapeutic Activation.—The risk of induction of arsenic-fastness and of therapeutic activation of the disease have been discussed by Beerman (1930) and by Milian. These observations are based on clinical experience nd on the laboratory ork of Bronfenbrenner and Schlesinger Klauder Brown nd Pearce and the clinical observations of Hoffmann and Milian. While such activation and resistance-inducing effects re comparat vely rare they are sharp w rning t the clinician t adhere t an adequate and if anything larger dosage scale scrupulously adjusted t eight and not t merely empirical standards, in the use of arsenical medication for the treatment of syphilis

THEORY OF THE REST INTERVAL

Intermittent *versus* Continuous Treatment.—The age-long battle between intermittence and continuity (no rest interval) treatment for syphilis is now approaching—if it has not actually reached—a decision in favor of the continuous side. Certainly in early syphilis the successful administration of total curative doses of neoarsphenamine and mapharsen in a single continuous procedure reduced to as little as five days without destruction of the patient has done away with many though not all of the toxicity objections to continuity in treatment. It is impossible any longer to sidestep the massive collection of statistical information represented by the studies of Moore and Kemp and the American Cooperative Clinical Group, as well as the League of Nations investigation in toto of the superiority of continuous over intermittent treatment in the early stages of syphilis. Granted that some form of therapeutic respite from the continuous administration of any one drug still has a tangible claim to consideration, ample provision for such respite can be made in the rotation or alternation of arsenical and heavy metal in all the current effective methods for the treatment of syphilis.

While such a statement is acceptable for early syphilis, late syphilis still remains a field in which impaired tolerance and constitutionally reduced resources may influence the choice between continuous and intermittent therapy. Here the rest interval may again come into its own. If nothing else the opportunity to recover from the toxic effects of treatment and to gain headway toward recovery from the disease by a succession of steps in which nonspecific processes probably play almost an equal part with the true specific or spirillicidal effects of treatment, can be observed at its best in the domain of late constitutional and particularly late neurosyphilis.

The so-called "intensive" (though comparatively speaking uniutensive or inadequate) systems of treatment such as those of Scholtz and Pollitzer, which have formed the basis of comparison with the Cooperative Clinical Group continuous material cannot be regarded as adequate examples of intensive treatment in the light of what is now becoming known about the massive dose or ultraintensified systems of intravenous drip and multiple injections given over five to ten-day periods. The older systems failed in that while they began intensively, they ended before the adequate total dose had been given, and interposed a rest interval for relapse before another fraction of the total dose was intensively administered. Apparently the eliminative mechanism for the drugs involved in the treatment of syphilis is adequate to practically any load placed upon it, even by the most intensive of present-day procedures, so that cumulative intoxication is rare, if it occurs at all, at least in the early phases of the disease.

COMBINED, SIMULTANEOUS, ALTERNATING AND OVERLAPPING TREATMENT

Combined Treatment.—Combined treatment is the term frequently used for a therapeutic regimen including two or more drugs or modes of attack in dealing with a syphilitic infection. Thus, the use of arsphenamine and mercury or arsphenamine and bismuth constitutes combined treatment. Such treatment, however, is not necessarily concurrent but may be alternate.

Alternate Treatment.—This is defined as combined treatment in which only one drug or method is used at any given time or in any given course, the next ensuing course employing another single drug or method of distinctly different qualities and potentialities. Thus, in combined arsphenamine and bismuth, the arsphenamine may be given alone in the first course, the bismuth alone in the second course, and on an alternating scheme arsphenamine alone

again in the third course and bismuth alone in the fourth course Simultaneous combined treatment would give arsphenamine and bismuth coincidentally as a single course and might then give one or the other drug alone in subsequent courses

Simultaneous *versus* Alternating Treatment.—Both continuous and intermittent treatment, since these two items concern the matter of rest intervals only may be given as combined simultaneous or combined alternating treatment.

Overlapping Treatment.—This is a compromise between concurrence and alternation. In an overlapping system a course may begin with an arsphenamine which is given alone for a variable number of injections and then given concurrently with several injections of a heavy metal The arsphenamine phase of the treatment then stops and the heavy metal is continued alone for a definite time to be again joined so to speak, by the arsphenamine before the end of the heavy metal course Thus the beginnings and endings of the arsphenamine and heavy metal courses overlap each other the treatment being both continuous, simultaneous and alternating in partial degree

The Combined Use of an Arsenical and a Heavy Metal.—The battle waged throughout the arsphenamine era between those who would depend exclusively on the arsenical (Leredde, arsphenamine 606) or exclusively on the heavy metal (Schwartz, bismuth) or in today's practice the proponents of the five-day drip and even the initial multiple injections systems (Hyman, Chargin, Leifer Eagle) is apparently in fair way to be won by those who support in one form or another the combined use of the two types of drug. Already students of hyperintensive treatment such as Shaffer are inserting bismuth into their multiple injection courses, and Moore Eagle and others, seeking to develop intensive systems in the interest of time-saving for the armed forces, are harking back to bismuth as the shortcomings of reliance on a single drug become apparent. The problem is by no means simple and the question of true synergism versus merely additive effects requires much further study Nonetheless, safe practice is definitely holding to the double life-line of two drugs used simultaneously concurrently or alternately with or without overlap. Thus it may still be announced as sound principle that an arsenical and bismuth treatment is to be preferred to either drug alone French experience, and the observations of the Breslau clinic during a period when treatment was restricted to bismuth, indicated the necessity for the arsenical from the standpoint of infection control, if not the cure of the disease It seems reasonable to believe that the Cooperative Clinical Group demonstration of the ultimate equality of effectiveness of the therapeutically less effective neoarsphenamine as compared with arsphenamine 606 was largely due to the supportive amplifying effect of the use of bismuth. The question of simultaneity as compared with alternation of administration seems in process of decision at this writing, in favor of alternation.

Kolmer has been able to demonstrate the marked stepping-up effect produced by the synergistic use in trypanosomiasis in rats of an arsphenamine with a comparatively ineffective mercurial. Both mercurophen and flumerin when administered with arsphenamine and neoarsphenamine markedly accentuated the trypanostatic effect, though both were used in lower doses than were required when the drugs were given alone Kolle obtained similar results in the use of neosilversalvarsan and novasurol in rabbits, and Voegtlin and Smith have observed the complementary action of arsenical and antimony compounds. Myers and Corbitt similarly reinforced the action of subeffective doses of neoarsphenamine with sodium and potassium tartro-bismuthate.

Schamberg (1929) and Harrison (1931) have for many years advised simultaneous arsenical and heavy metal therapy Bernard (1928) believed that concurrent treatment yielded less neuro recurrences and Lehnhoff Wyld (1924–1926) found the trypanocidal action of sulfarsenol was greater when any of a variety of other metals was in the circulation at the same time than when it was given alone Belding (1931) found that the serologic results were best when combined arsphenamine and mercury treatment was used in preference to either drug alone Belding's paper however, does not make it clear whether he used simultaneous combined or alternating combined treatment. In a careful experimental study on rabbit syphilis, Clausen, Longley and Tatum (1932) of the University of Wisconsin, using combinations, administered simultaneously of fractions of the minimum curative dose (M.C.D.) of an arsenical with fraction of the M.C.D. of bismuth

preparation, were ble to determine the quantitative nature of the combined therapeutic action of these two types of compounds. They found that it was one of simple addition rather than potentiation or inhibition. On the other hand, the cotoxicity of bismuth and arsenical compound was found t be less than additive nd that the cotoxicity of an arsenical with a more slowly beorbed bismuth compound is much less additive than with preparation more rapidly absorbed. These findings indicate t the Wisconsin group that there is greater margin of safety hen the drugs are used concurrently than when either is used alone in correspondingly effective doses.

On the other hand, there is much recent evidence t show the disadvantages of combined (simultaneous) treatment. In 1930 Beerman demonstrated what had been repeatedly emphasized before (Felke 1922 Schreus, 1923 Hoffmann and Schreus, 1923 Szecsi, 1923) that bismuth had some restraining effect on the serologic action of the arsenical. This was confirmed in more extended series by Beerman (1932). This effect, however may be due to reduced dosage or because of inferior drug. Beckh and Barnett (1930) made the more significa t observation that the incidence of relapse both clinical and serologic as greater among patients given concurrent treatment. Beckh and Kulchar (1939) from their experience with 18 patients resistant to three different arsenicals, including arsenoxide (mapharsen) found that more cases occurred after combined (simultaneous or concurrent) than after the alternating plan of treatment. Furthermore in spite of the definite theoretical adva tages of combined over alternating treatment, practical experience has forced us to abandon the former and accept, as standard American practice the alternating system of treatment (with overlap)

THE "ARSENICAL RULES

From the foregoing consideration it is now permissible in the light of the present-day knowledge of the mode of action of arsphenamines and heavy metals, to propose four great and practically inviolable rules governing the employment of the trivalent arsenical group of drugs in the treatment of syphilis.

Rule I.—Never use an arsphenamine exclusively or end a course of treat ment with it. Always use a heavy metal in conjunction or sequence.

Rule II.—Never use an arsphenamine insufficiently—that is, in a single short course Either give a long course of the drug or if short courses seem more advantageous, cover the possibilities of relapse thoroughly by the use of a heavy metal. The short, single course of arsenical early or late in the disease not properly combined with or followed by heavy metal, is too apt to give all the disadvantages and none of the advantages of this group of drugs.

Rule III.—Use an arsenical with utmost caution, and initial very low dosage and gradual increase when there is reason to fear either therapeutic shock or therapeutic paradox. Preferably prepare the way with a heavy metal (see p 220) always reduce the initial dose of arsphenamine to one half the full or adult dose or even less and do not use an arsphenamine at all in the late case until, if ever it is possible to envisage clearly a lasting beneficial effect.

There is an increasing tendency th the advent of mapharsen, t disregard, belie prematurely this rule

Rule IV —Never use an arsphenamine in a therapeutic test for diagnosis where its nonspecific effect, by producing improvement in other conditions may lead to confusion of diagnosis with respect to syphili

PRINCIPLES UNDERLYING THE THERAPEUTIC TEST FOR SYPHILIS

Rul IV Elaborated.—The therapeutic test is so closely related to the treatment of syphilis and to both its specific and nonspecific effects, that the following summary of its principles is given

again in the third course and bismuth alone in the fourth course Simultaneous combined treatment would give arsphenamine and bismuth coincidentally as a single course and might then give one or the other drug alone in subsequent courses

Simultaneous *versus* Alternating Treatment.—Both continuous and intermittent treatment, since these two items concern the matter of rest intervals only may be given as combined simultaneous or combined alternating treatment.

Overlapping Treatment.—This is a compromise between concurrence and alternation In an overlapping system a course may begin with an arsphenamine which is given alone for a variable number of injections and then given concurrently with several injections of a heavy metal The arsphenamine phase of the treatment then stops and the heavy metal is continued alone for a definite time to be again joined so to speak, by the arsphenamine before the end of the heavy metal course Thus the beginnings and endings of the arsphenamine and heavy metal courses overlap each other the treatment being both continuous, simultaneous and alternating in partial degree

The Combined Use of an Arsenical and a Heavy Metal.—The battle waged throughout the arsphenamine era between those who would depend exclusively on the arsenical (Leredde, arsphenamine 606) or exclusively on the heavy metal (Schwartz, bismuth) or in today's practice the proponents of the five-day drip and even the initial multiple injections systems (Hyman, Chargin, Leifer Eagle) is apparently in fair way to be won by those who support in one form or another the combined use of the two types of drug Already students of hyperintensive treatment such as Shaffer are inserting bismuth into their multiple injection courses, and Moore Eagle, and others, seeking to develop intensive systems in the interest of time-saving for the armed forces, are harking back to bismuth as the shortcomings of reliance on a single drug become apparent. The problem is by no means simple and the question of true synergism versus merely additive effects requires much further study Nonetheless, *safe practice is definitely holding to* the double life-line of two drugs used simultaneously concurrently or alternately with or without overlap. Thus it may still be announced as sound principle that an arsenical and bismuth treatment is to be preferred to either drug alone French experience and the observations of the Breslau clinic during a period when treatment was restricted to bismuth, indicated the necessity for the arsenical from the standpoint of infection control, if not the cure of the disease It seems reasonable to believe that the Cooperative Clinical Group demonstration of the ultimate equality of effectiveness of the therapeutically less effective neoarsphenamine as compared with arsphenamine 606 was largely due to the supportive amplifying effect of the use of bismuth. The question of simultaneity as compared with alternation of administration seems in process of decision at this writing in favor of alternation.

Kolmer has been able to demonstrate the marked stepping-up effect produced by the synergistic use in trypanosomiasis in rats of an arsphenamine with a comparatively ineffective mercurial. Both mercurophen and flumerin when administered with arsphenamine and neoarsphenamine markedly accentuated the trypanostatic effect, though both were used in lower doses than were required when the drugs were given alone Kolle obtained similar results in the use of neosilversalvarsan and novasurol in rabbits, and Voegtlin and Smith have observed the complementary action of arsenical and antimony compounds Myers and Corbitt similarly reinforced the action of subeffective doses of neoarsphenamine with sodium and potassium *tartro-bismuthate*.

Schamberg (1929) and Harrison (1931) have for many years advised simultaneous arsenical and heavy metal therapy Bernard (1928) believed that concurrent treatment yielded less neurorecurrences and Lehnhoff Wyld (1924–1926) found the trypanocidal action of sulfarsenol was greater when any of a variety of other metals was in the circulation at the same time than when it was given alone. Belding (1941) found that the serologic results were best when combined arsphenamine and mercury treatment was used in preference to either drug alone Belding's paper however does not make it clear whether he used simultaneous combined or alternating combined treatment. In a careful experimental study on rabbit syphilis, Clausen, Longley and Tatum (1942) of the University of Wisconsin, using combinations, administered simultaneously of fractions of the minimum curative dose (M.C.D.) of an arsenical with fraction of the M C D of bismuth

not discharge it completely or sometimes even partially by the most detailed and painstaking instruction of the patient.

The facts involving the cooperation of the patient are included in Figure 212. Two studies of infectious relapse from the standpoint of physician-patient responsibility undertaken in our clinic have indicated that responsibility for lapse in treatment, which is the usual starting point of infectious recurrent lesions, is approximately equally divided between physician and patient.

Failure to inform the patient fully of the facts; unwarranted assurances based on the first or subsequent negative serologic tests; survivals of the conception of abortive cure leading to shortened treatment, and frank ignorance of the management of syphilis by modern methods were the items in the bill against the physician. In the analysis from the patient's standpoint by Pugh, Brown *et al.*, *failure to realize the seriousness of the disease* ranked with the discomforts of reaction to treatment as the *foremost* of the reasons *for failure to* carry treatment through to discharge. The worth of ethical pressure, while often overestimated, is by no means to be despised, and the wise and effective physician treating a patient to control infectiousness, spares (or extension of time between date of infection and the patient's resumption of sexual activity by every device known to the temple, the court, and the sawdust trail. When once, in his best judgment, the physician has authorized sexual activity, he should strive to keep check upon it, in the early years particularly, limiting it to the times when the patient is under arsenical control, if possible.

THE CONTROL OF INFECTIOUSNESS IN SYPHILIS

A Résumé of Known Principles

Because of its importance in the control of syphilis as a disease, and especially because of its significance in marriage and prenatal testing law decisions, the following summary of existing knowledge regarding the control of infectiousness in syphilis is prepared.

1. *The person with infectious syphilis has acquired the disease from another in the same condition, and will, in all probability, pass it on to an uninfected person.* This then, is the first principle of the epidemiology of syphilis, and the first principle of its control is that *contact should be traced both ways, to and from the infectious case.* The technic of contact-tracing, while to some extent a matter of individual interest and aptitude on the part of the physician who first sees the infectious patient, can also be turned over to trained public health nurses who will conduct the work in a manner that can give no offense to any reasonable physician or patient. *The State Division of Syphilis and Genito-infectious Diseases is prepared to provide contact-tracing and follow-up service on request, for any physician.*

2. It is critically important to remember that *blood tests for syphilis do not identify, define or have any necessary relation to the infectiousness of the disease.* In the chancre stage, and infectious relapses later in the course of the disease among certain patients, serologic tests may be occasionally, frequently or constantly negative, yet the disease be actively transmissible. The reverse statement is equally true that the serologic tests may be occasionally, frequently or constantly positive without any infectiousness whatever. This is especially true of late latency, late visceral, vascular and neurosyphilis, and congenital or prenatal syphilis.

3. *There are no absolute rules or statements with regard to infectiousness to which occasional exceptions may not be found.* It is necessary therefore, to be on guard constantly for the possibility of infectiousness, even where it seems unlikely, and absolute statements with regard to non-infectiousness should be made with caution and with due regard for their probable, rather than absolute, character.

4. *Time and treatment are the controlling elements in the infectiousness of the disease.* In terms of stages, the primary, secondary and early latent periods are those of maximum infectiveness. Considered in terms of time, current evidence tends to indicate that 84% to 97% of the infectious lesions of the disease occur within the first two years. On the other hand, closer observation and study of relapse and recurrence may necessitate some revision of this statement in terms of patients who remain infectious for from five years to a decade or more.

5. *Infectiousness in prenatal or congenital syphilis is confined* for practical purposes and so far as present knowledge goes, to the eruptive manifestations of the first year of life. The male

Reprinted from "Pennsylvania Health," Vol. 1, No. 2, April, 1940.

*

congenital syphilitic passes rapidly into the category of late syphilis, so far as transmission of the disease is concerned, and as a child, adolescent, and adult, does not so far as is known, transmit the infection. The female congenital syphilitic, even though untreated, transmits the infection to her partner only with the greatest rarity and practically never to her child. Third generation syphilis is among the reportable rarities of the disease. In any event, adequate treatment for prenatal syphilis should offer full protection.

6. *While infectiousness in late latent and late active syphilis is accepted as extremely rare*, infectious transmission has been recognized in a paretic as long as twenty-six years after infection. It must be apparent therefore that *the history of an individual patient with reference to relapse is an important consideration in deciding the probabilities in his case.*

7. *Infectiousness in women has some important special phases.* First, the onset of the disease, and even quite a proportion of the secondary manifestations occur in the genital tract where they are invisible to the patient, and not searched for by the physician. The Negro woman is particularly known for her predisposition to mucocutaneous infectiveness. It may be obvious therefore, that control of infectiousness as a public health problem in syphilis will have much smaller possibility of success through the attempt to recognize and control this status in women than it will in men. *Every effort should be concentrated therefore not only upon the adequate examination of the female patient for infectious lesions but upon the control of infectiousness in the male.*

Relatively little is known of the carrier stage of infectiousness in women (i. e. infectiousness during latency). The female genital tract may conceivably serve as a carrier of infective material even in a patient who is not outright infectious by virtue of her own disease.

8. *Infectiousness of the Pregnant Syphilitic Woman for her Child.* The intimacy of the inter changes between mother and fetus, notwithstanding the probable partial value of the placental barrier makes infectiousness in the woman from the standpoint of the child so unamenable to rules or categorical statements that *current practice accepts the necessity for anti-infectious treatment of the mother during pregnancy as routine for the protection of her unborn child.*

9. *The infectious lesions of syphilis are largely those of the mucocutaneous surfaces.* Lesions intrinsically non-infectious at the start may become so through erosion, even on the glabrous skin, and in the folds of the body. The mucous patch and the eroded or hypertrophic papule (the latter constituting the flat condyloma, so-called), all of these lesions characteristic of the secondary stage and the relapses of the early latent period, are particularly menacing because of their transient and symptomatic character, their easy confusion with other conditions, and the ease with which they are overlooked altogether in casual examination and in sexual contacts. The primary lesion of syphilis is infectious from the start and may even through erosion in coitus or otherwise after it has actually healed, again become a source of infection. It should be recalled that the primary lesion of syphilis may be inconspicuous and fail entirely to attract the attention of the patient, and even the physician. The primary lesion in the *female* has the reputation of being particularly evanescent and inconspicuous.

10. *The presence of the Spirochaeta pallida can be demonstrated in many lesions* in which it is hardly customary as yet to institute darkfield examinations. Papular lesions about the genitalia which are not actually eroded or condylomatous, can be scraped and examined by darkfield often with convincing demonstration of the organism. On the other hand, it is important to remember that saprophytic spirochetes are common in both the mouth and genitalia, and such examination as the darkfield should be expertly interpreted. *Kits for the collection of such material are supplied by the State Public Health Laboratory on request, and examination of material collected in accordance with directions will be promptly reported.*

11. *The infectiousness of blood, secretions and exudates* is probably not as great as is often believed. On the other hand, any secretion, excretion or discharge which passes over an infectious lesion may contain *Spirochaeta pallida*, and such fluids as blood, breast milk and the like may contain the organism so erratically and unpredictably that their infectiousness during the infectious period of the disease should be more or less taken for granted. This is particularly true in operative and transfusion work and in injuries to physicians or other personnel involving needle-pricks with infectious blood contamination, droplet or contact contamination and so forth. *The State Division of Syphilis and Genitoinfectious Diseases will advise by wire, collect, on request, as to the course to be pursued in an individual case in which it is feared that the disease has been transmitted by infective material of this kind.* The necessary information to be supplied with the inquiry is as follows.

1. Description of the accident, including handling of the infective agent before, and after.
2. Description of the source of infected material, including evidence of the disease, and stage or duration of the infection, if a patient.
3. Any previous treatment of the infective source or patient with dates.
4. Treatment given the victim of the accident.

12. *The infectiousness of semen* has not thus far been finally evaluated, and it is certainly much less than has been believed. It is not believed at the present time that syphilis can be transmitted to the ovum by semen of an infected male. This disposes for the time being of the conception of paternal transmission to the child via an uninfected mother.

13. *Physical conditions for infection transmission in syphilis* are difficult to define and contain many elements of the unexpected. Where it is feared the disease has been transmitted it may not be, and conviction of absolute safety or unawareness in a given situation is often at the bottom of an infection. No absolutely dry material can transmit the disease. Moisture and relative anaerobiosis appear to be necessary conditions. Refrigeration does not destroy the organism for a considerable period, so that autopsy material may be dangerous. A fluid containing organisms deposited upon a moist surface offers the maximum risk of infection. For that reason, in practice, kissing and sexual intercourse are the primary modes of transference. Glasses, pipes, silverware, razors, may function in this way. Bizarre intermediate transmission is not excessively rare, and the picking up and inflation of a condom on the street has been known to lead to primary infection in a child. Dishes, glasses, and similar intermediary materials, if thoroughly washed in hot water and soap do not transmit the disease.

14. *General Precautions against Infectiousness.* The infectious lesions of syphilis can be made less dangerous, first, by reducing their frequency; second, by instructing the patient regarding their whereabouts and appearance, and third, by impressing upon him from the start, the importance of his cooperation in treatment regularity. Infectious lesions are relatively common in some patients; relatively rare in others, but unfortunately, except for the racial difference previously mentioned, no means of predicting with accuracy the tendency to infectious lesions in an individual case exists. *Observation of the patient, however, over a period of months,* offers the following guides:

1. *Very early reversal of the serologic test* for syphilis under treatment (negative blood before the eighth week) is indicative *of a relapsing tendency,* possibly infectious.
2. *Slowness in resolution of infectious lesions,* particularly the chancre, is a warning of infectivity due to treatment resistance. Every patient under treatment for early syphilis should be closely observed for the rate at which lesions heal. The physician will occasionally be surprised by the failure of an active arsenical to cause involution of obviously infectious lesions, not only after one or two, but after many injections.
3. *Dirt and irritation locally,* whether in the mouth or about the *genitalia,* favors the production of infectious lesions.
4. There is reason to believe that *the free use of alcohol* has some tendency to predispose towards relapse.
5. *The seropositive primary stage of syphilis,* before the development of secondaries, which is the stage of the disease in which most infection tends to be discovered at the present time, is the most prone to relapse under treatment of any aspect of the disease. Accordingly *patients who begin treatment with a seropositive chancre before the appearance of secondaries, must be especially warned,* especially supervised, and receive especially prolonged treatment with special regularity if their infectiousness is to be adequately controlled.
6. *The smoking and chewing of tobacco has been known* for many years to predispose to the development of infectious lesions in the mouth.
7. Since the infectiousness of semen and of vaginal discharges is not clearly understood, the use of a condom in coitus should be uniformly advised for all persons within the average infectious period *of* the disease, and for all persons exposing themselves sexually to risk of infection.

TREATMENT CONTROL OF INFECTIOUSNESS

1. It should be emphasized that no amount of instruction to the patient and no amount of pains and particularly in examination on the part of the physician can take the place of effective modern treatment in the control of infectiousness in syphilis. In fact, *through contact-tracing of the infectious person and treatment control of infectiousness itself lies the only existing avenue to the control of the disease.*

The following briefly summarizes the principles involved: ( ) infectiousness in syphilis is controlled by the arsphenamines and arsenoxide, *and by no other drug or treatment with even approximate effectiveness.* These drugs should therefore form an integral part and in general, the initial part of the treatment of all infectious or potentially infectious persons. The dosage of these drugs must equal or exceed a minimum of 0.3 gram neoarsphenamine or arsphenamine and 0.05 gram of arsenoxide (mapharsen) if infectiousness is to be controlled in the average adult, and the dose

should be rapidly increased to the therapeutic maximum. Do not begin treatment with minute doses, for treatment-fastness may result. (b) *The heavy metal element in treatment*, including bismuth and mercury (preferably bismuth) *is useful in combination with the arsenical, but ineffective alone in controlling infectiousness* If an arsenical cannot be used (and this is exceedingly rare) water soluble heavy metal salt such as sodium bismuth tartrate or mercury dichloride or succinimide given frequently intramuscularly is the best heavy metal choice for the control of infectiousness. All other heavy metal preparations are to be regarded merely as adjuncts in infection-control and not as mainstays. ( ) *T factors are of vital importance in the arsenical control of infectiousness: first, regularity and continuity of treatment, and second amount and duration of treatment.* An enormous decrease in the percentage of infectious relapse follows as little as five to nine weeks of arsenical treatment in effective dosage. On the other hand, to obtain anything even approximating reasonable public health standard of infection-control, not less than 20 intravenous arsenical injections are necessary accompanied by corresponding number of heavy metal injections, preferably bismuth. This estimate of "20-40, originally measure of statistical convenience has had considerable publicity as minimal standard in treatment for non-infectiousness. N conclusive evidence exists that this minimum amount of treatment is adequate. (d) *Treatment to non-infectiousness, while recognized public health desideratum*, has no *absolute standards of time, dosage or number of treatments*. In fact, it is impossible to define form or amount of treatment which absolutely insures non-infectiousness. For that reason it is advised that the physician treating patient for the control of infectiousness, *aim at the standard for cure rather than at anything short of it*.

2. *Both in treatment for the control of infectiousness, and in treatment for cure, absolute continuity without lapse or rest interval has* been proved both by international and American investigations *to be the optimum procedure*. The introduction of lapses, for which the patient is responsible or rest periods, permitted by the physician, enormously increases the risk of relapses, of treatment fastness, and ultimately uncontrollable infectivity

3 *The amount of treatment now recognized as reasonable standard* is defined as thirty intravenous injections of an effective arsenical in effective dosage; sixty intramuscular injections of an effective bismuth salt (for example, bismuth subsalicylate) distributed in alternating courses over period of not less than one year followed by two years of treatment observation. This statement is subject to modification dependent on the development of the still experimental systems of intensive treatment (see Chapter XIV) This constitutes treatment aimed at cure, and is recommended the ideal for the control of infectiousness. Where this ideal cannot be attained, the largest number of arsenical and heavy metal injections in effective dosage and continuously given, over the longest period of time should be the practical goal

4 *The control of infectiousness in early latency* (first four years of the disease) requires treatment approximating that for primary and secondary syphilis. In the later years of latency the public health standard calls for approximately 24 injections of the arsenical and much more prolonged use of heavy metals (approximating 80 to 100 injections) for best results.

5 *A recommended standard of treatment for patients seen in the seropositive primary stage* (more resistant and prone to relapse than other early stages) is 40 intravenous injections of the arsenical, with 60 injections of the heavy metal. Especially close observation during the post treatment period of probation in such cases is desirable.

6. *Control of infectiousness pregnancy* cannot be made matter of rule but continuous treatment throughout the pregnancy approximating ten intravenous injections of the arsenical and ten intramuscular injections of oil-suspended bismuth salt (preferably the subsalicylate) is satisfactory average requirement. Its applicability is of course conditioned by the circumstances of the individual case but continuity without lapse or rest intervals, and the termination of treatment just before term with an arsenical rather than heavy metal are essential.

7 *Serologic Relapse and Infectiousness* While early reversal of positive blood test to negative may arm of relapsing or treatment resistant tendency and while fluctuating serologic tests during intensive treatment also indicate resistant infection, both physician and patient should be cautioned not to accept one or many negative tests as evidence of non-infectiousness, or at the other extreme to interpret fixed or treatment-resistant positive as necessarily evidence of infectiousness Time and the character amount and regularity or continuity of treatment, together with the recognized course of the individual patient case under repeated observation, are far more important guides.

8. *The foreshortened intensive (1–5 day and 12–26 week) systems* of treatment for syphilis ordinarily render the patient noninfectious in the same time as that required by the longer standard systems. There exists, however because of the early discharge of the patient while he is still within the theoretical period of greatest probability of infectious relapse very serious problem calling for the closest follow up of the once completely treated and asymptomatic patient.

Observational Control and Infectious Relapse *vs* Reinfection under Intensive Systems.—Proponents of intensive systems are apt to lose sight of the obligation to maintain two years minimum check on the recurrence of infectious lesions in their patients and in any event the observation to which such patients are subjected will not be as intensive as the week-to-week check that can be maintained on those who follow strictly the requirements of the longer standard systems. The observed great increase in frequency of so-called "reinfection" in patients who have been treated by the foreshortened intensive technics arouses the suspicion that these patients are in reality the victims of infectious relapse rather than reinfection and emphasizes the redoubled necessity for observation and caution in interpretation. For statistical purposes in evaluating these methods with reference to the control of infectiousness, reinfection which is notoriously difficult to prove, should be set aside in favor of the interpretation of infectious lesions observed after intensive treatment, as *relapse*. The disposition to relax the existing criteria of reinfection in order to put a better face on possible relapse following intensive systems, is to be regretted.

The transmission of syphilis in industrial relations as such is probably of small moment. Where the sexes work in contact, it is more important to attack the social hygiene problem than the epidemiological one through the instrumentality of matrons, effective shop discipline education. Even in food handlers and cosmetic workers (see Chapter XXIII on Public Health) the risk of transmission in syphilis may be exaggerated though it is true that one sometimes shivers when he watches the technic of barbers dining-room, kitchen and soda-fountain help from behind some scenes. Periodic serological testing of such persons is probably desirable for detection purposes. The most tragic aspect of the matter is the least known—the children infected by irresponsible and immoral servants in the home. We have seen everything from tabes in the house-mother of a great girls school dormitory to a chancre on the penis of a two-year old-baby traced to the activities of the crooked and infected nurse. Here at least is a field that merits genuine effort at study and control and one to which the physician alone in contact with the family life has real access.

ROLE OF TECHNIC AND CHOICE OF METHOD

"Smoother Treatment."—Hurting the patient in any therapeutic procedure is, in cumulative effect, a serious matter. The things that the dull needle, the mishandled spinal puncture and the lumpy painful butt do daily to the effective treatment and the hope for extermination of syphilis, have never yet been successfully estimated. Side by side with technical adequacy must go the thorough familiarity of the physician with his drugs. Grave injury and death lurk along the border of a modern course of treatment, waiting to take advantage of seemingly the most trifling oversight. No apology therefore need be made for commending technical perfection as described later to the physician who expects to treat syphilis effectively.

Systematized Treatment. Some Principles Governing Choice.—In connection with an attempt at evaluation of foreshortened intensive systems of treatment for early syphilis, a statement of principles was drawn up (Stokes 1942) which has more or less general application to the choice of treatment methods in their relation to morbidity mortality control of infectiousness and cure.

1 Syphilis cures itself or at least comes to seronegative arrest with little damage, in an unknown percentage of cases, probably ranging around 40 to 50 per cent.

2 A relatively small amount of treatment, if it does not of itself bring on relapse in one form or another through disturbance of the defense and immunity reactions is capable of raising the expectancy of cure to an unknown but considerable degree. *In seronegative primary syphilis this may well be guessed* to be as high as 70 per cent, to judge by the good results so widely reported for the now out of date "abortive cure systems.

3 Any system no system and even no treatment at all in syphilis has a running start toward cure, then The intensification and the prolongation of treatment that expresses itself in 1200 milligrams in five days or thirty arsenical and sixty bismuth injections in eighteen months is directed at a relatively small segment of unpredictably resistant infections These resistant infections will either (*a*) maintain the reservoir of infective disease by relapse, (*b*) be responsible for infected children or (*c*) lead to serious consequences especially in the cardiovascular and nervous systems of adults

4 Any new systems proposed should be judged basically by their ability (*a*) to equal or surpass the curative" expectancy of the old ones, (*b*) to lead to less infectious relapse (*c*) to cure more mothers and protect more children, (*d*) to reduce the incidence of cardiovascular and neurosyphilis and (*e*) by their relative risks to the patient.

5 For the evaluation of a system, time and observation are necessary to establish reduction of or absence of relapse and progression. For the former two to four years, for the latter up to ten years is a reasonable observational requirement. For decision on relapse the patient must be repeatedly and frequently observed, for it is a come and go affair For the evaluation of "cure" from a decade to a lifetime the longer the better is required

6 A system which under such scrutiny has shown itself at least equal to its predecessors may then proceed to claim additional advantage and support for a variety of reasons including cheapness rapidity controllability of the lapse factor because the whole job is finished in a short time and in the widening of availability of treatment by making possible the treatment of more persons per unit of time, personnel and equipment. Such considerations are in the main secondary to those of control of infectiousness and real curative power

7 If the new system equals the old or surpasses it in all these particulars it has but one more hurdle to make before achieving priority While *primum non nocere* is losing some of its meaning in a war torn world there are still arch conservatives who are inclined to examine critically the bad effects, the complications of a system. Of real importance to the victim are the risks involved the chances of damage or of death from treatment in the case of a disease which with none or very little treatment gives the victim at the outset a 40 to 70 per cent chance of escape from serious consequences. If an equal chance of escape with an older method offering less risk exists, only the most cogent reasons and a free choice by the patient justify the selection of the more dangerous method

What is an experimental method? A method remains in the experimental zone syphilotherapeutically speaking (*a*) until everything that can be found out on animals has been found out, including the direct effects on both the disease and its carrier of the method itself actually applied While the results

of trial on animals may prove disappointing equivocal and for various reasons inapplicable to man methods must be tried on animals to see whether the results are interpretable or not. (b) The method must next be applied to man using the lessons learned from animals. (c) When thus applied the method must now show its morbidity and mortality for man clearly and unmistakably and (d) its efficiency in man must be judged by the criteria enumerated

SEROLOGICAL CONTROL OF TREATMENT

In order to provide at this point, among the principles of treatment, a résumé of the many considerations bearing upon serological control, Fig 66 has been prepared as a semischematic and to some extent unavoidably dogmatic itemized statement of current conceptions. The detail of the response of serological tests to treatment was discussed at considerable length in the preceding chapter (IV) and the reader is urged at this point to combine the foregoing summary with the material just mentioned in a thoroughgoing review of the principles involved inasmuch as they are essential to all discussion of treatment in subsequent special chapters.

THE GENERAL RESPONSE AND PROGNOSIS OF SYPHILIS UNDER TREATMENT

Symptomatic Results of Modern Treatment.—The treatment of syphilis, to one at all initiated is one of the truly consoling and gratifying phases of the medical art. It is seldom indeed that the physician discovering syphilis in a symptomatic complex, does not draw a breath of relief and congratulate the patient on what might seem to the victim to be a subject for condolence instead The conditions that make no response to treatment in syphilis are almost nonexistent. Primary optic atrophy and the advanced well-established cases of tabes dorsalis, together with the effects of old chorioiditis, eighth nerve deafness and the irreparably damaged heart and vascular system, are almost the only phases of the disease in which the skilled therapist is as yet unable to justify himself Skill unquestionably plays a part in the consummation of this optimistic prognosis and an inappropriate selection of methods is sometimes all that is required to bring on disaster instead of relief A temporary good effect, as in the therapeutic paradox, may be replaced by ultimate catastrophe under injudicious management.

At the risk of drawing the fire of ridicule from our syphilological colleagues who appreciate the speculative intuitive intangible and uncontrollable factors in such a tabulation and the inner meaning of the ranges of variation involved, we present a summary of average expectancy in therapeutic results as we have seen them obtained by the standard methods dealt with in this book (Fig 67) The tabulation should be read as follows

"Acute interstitial keratitis 25 to 50 per cent improvement is expected in four to six weeks therapeutic effect ranging from 20 per cent impairment (−20) to 80 per cent improvement is to be expected in average cases within from four months to two years 60 per cent of cases achieve good results."

The occasional brilliant result or exceptional failure is not included in the estimates.

A percentage of −100 means an absolutely bad result, or death when the lesion can be a cause of death. The immediately fatal result may of course be averted in most cases by careful management, but the late deaths express the therapeutic paradox discussed in subsequent chapters The "minus 20

Fig 60.

THE SEROLOGIC CONTROLS OF TREATMENT—A SUMMARY OF PRINCIPLES

1 Never deify th serologic record of case ("paper syphilis) in treatment or mistak the test for the disease
2. Never use a serological test alon treatment guide in early syphilis or the only deciding point t y time
3. Use every effort t make diagnos and begin treatment i earl syphilis before the patient becomes seropositive This is the "Golden Opportunity
4. Treat early syphilis to an empirical maximum by system regardless of serological response treat late by the stat of the patient as whole
5 In all pparently seronegative primary syphilis, repeat the blood serologic test on the first or second day following the first arsenical injection. If positive regard the case seropositive primary instead of seronegative.
6 Place no reliance whatever on serological results grades t infectiousness (except warning of impending or actual relapse) i known syphilitic persons.
7 Avoid taking test before the 15th to 20th arsphenamine injection in early syphilis unless certain that the patient will continue if negative ("fiscal landmark")
8. In foreshortened intensive (five-day to ten-week) systems for early syphilis, quantitative serologic tests should if possible be employed t follow the titer of reagin during the period of observation after the completion of the treatment course
9 A too easily reversed serological test especially in early syphilis may indicat relapsing tendency and a poor defence.
10. Weak positive tests are important in early syphilis.
11. Irreversible positives require ( ) spinal fluid examination (b) lifelong observation with ( ) yearly complete syphilological ppraisal.
12. Asymptomatic fixed positives must be judged by their time factors and given treatment in general for protection against possibilities. Avoid activating quiescent infection by inadequat or unsupported treatment.
13 A fixed positive need not mean danger or death.
14. False positives, strong or weak, may occur in treatment as in diagnostic work.
15. Watch th heart and liver in an early case marked by occasional slight positive recurrences in series of negatives.
16. When treatment is suspended take tests as often in early cases patient will permit (at least quarterl) in lat cases indicated.
17 A provocative procedure if negative is no proof of cure, cannot detect an uncured case
18 It may be necessary to treat a persistently seronegative case because symptoms progress under cover of negative serology
19 In the presence of signs or suspicion of serious lat syphilis, even though seronegative begin treatment th heavy metal.
20. Place no early case on rest period or lat case on observation ithout spinal fluid examination if obtainable
21. Try to secure spinal fluid examination at least bet een the sixth t t elfth month of an early infection, and repeat in one year if negative
22. In asymptomatic latency where the positive blood test has made the diagnosis, never if voidable begin treatment without trying t obtain spinal fluid examination. If unobtainable begin treatment ith heavy metal, not arsphenamine
23. Remember th slight rise in cell count, and the red flag (preparetic) picture in the spinal fluid (pp 118, 119)
24. Sensitive test procedures are allowable treatment control
25 Both complement fixation and precipitation types of test should be sed The Kolmer W ssermann modification and flocculation procedures re ommended covering each other d screpancies.
26. Discrepancies (serological discord) are to be expected in lat and treated cases.
27 N series of negatives can exclude the need for spinal fluid control in treated cases.

NO SERIES OF NEGATIVE TESTS ALONE CAN EVER MEAN "CURE.

per cent" in the case of the chancre allows for the therapeutic shock (Herxheimer) in the first twenty-four hours specified.

The Meaning and Possibilities of Relapse.—Syphilis is the relapsing disease par excellence and every reflection on its prognosis must be colored by this qualification. In fact, the physician increases his effectiveness in no small degree in proportion to the extent that he has absorbed this maxim and put it into practice. He should school himself to a constant and systematic alertness a habit of search for signs of relapse which makes it impossible to dismiss a patient under observation with verbal assurances based merely on a negative blood serological test, for example. Search for evidence of relapse should be as objective and painstaking as search for the diagnostic signs of the disease in the first place. Relapse is serious for the social order early in the disease and often especially serious for the patient because it finds him deprived by the quick destruction of most of his organisms of the resistance-

building forces provoked by their presence in his tissues. The patient's contacts thus become the victims of his recurrent infectiousness, while he himself through a strategically situated focal relapse in an unprotected structure like the nervous system may be crippled for life. Inadequate and poorly systematized or unwisely directed treatment of the disease forms very properly the material for a special discussion (Chapter XIII). On the other hand the physician who encounters a relapse at some point where he least expects it or where he believes it most completely guarded against, should not lose faith in treatment or assume an uncritically pessimistic outlook toward the control of the disease. Relapse is an inevitability in syphilis in a certain proportion of patients in every phase and stage, and no device, ancient or modern, can completely prevail against it.

The Influence of Modern Treatment on Prognosis.—Symptomatic results have been drawn on time and again by conservatives not only for their own worth but to give credit to the inference that letting the disease alone or at best interfering in only the slightest degree, as with mercury pills and iodide, for example, with its normal course leads to a high proportion of long lives free from significant complications. While there are in all phases of the disease and under all methods of treatment instances in which a single arsphenamine injection healed a chancre and "cured" the patient, or a few pills and iodide given in the twenties left a man robust in the eighties, these striking examples that rise so readily to the lips of the "Old Guard" cannot be accepted as establishing the case for an utter disregard of prolonged and intensive treatment *as a guarantee of safety*.

It is very interesting to note in the literature the decline of reminiscent articles dealing with the benign course of syphilis in the prearsphenamine era since 1921, at which time, both in this country and abroad, the results of the first decade of arsphenamine therapy were in process of collection and publication. Extremely interesting reviews of the course of syphilis under régimes of minimal treatment, or no treatment at all, have been made by Blaschkow, by Lesser and by Bruusgaard (1929). Fournier and Neisser at the height of the mercurial era had, with an almost exact correspondence of their percentage figures, shown that among tabetics and paralytics approximately 55 per cent had received no treatment and 40 per cent very little treatment, while only approximately 5 per cent had received repeated courses of mercury. A famous statistical series of Mattauschek and Pilcz, who studied syphilis among Austrian army officers, included 1188 patients in whom, for example, the incidence of paresis was 23 per cent in the untreated and those receiving only one course of mercury, as compared with 5.83 per cent in those receiving repeated courses. Similar figures applied to other aspects of neurosyphilis in their group. Turning more specifically to the comparisons between the mercurial and the arsphenamine era, Des Brisay and Stokes, and Barner and Stokes undertook statistical studies of the prognosis of syphilis from the material of the Section of Dermatology of the Mayo Clinic in an attempt to satisfy themselves on this point. The controls in such an investigation are exceedingly difficult, but even allowing for the defects thus introduced, Des Brisay and Stokes found from a study of about 500 cases that untreated syphilis runs a definitely less favorable course than treated syphilis. Fewer than 1 per cent of 208 untreated cases had attained serological and symptomatic cure. After treatment by mouth 6 per cent were totally arrested and 10 per cent had attained serological negativity on blood and spinal fluid. Of 178 who had had modern but none the less entirely inadequate and desultory treatment, nearly 18 per cent were serologically negative on the blood as against 9 per cent of untreated cases, and 10.5 per cent of patients treated by mouth. In syphilis treated by modern methods even improperly applied, considerably less than half as much cardiovascular, visceral, osseous and cutaneous syphilis developed as in untreated and mouth-treated syphilis. A patient with syphilis treated by mouth *evidently relies quite largely on his physiologic defence*. It would seem, then, from their results, that even a little treatment is better than none.

Bruusgaard's statistics (1929), based on the after-histories of the cases of early syphilis that attended the clinic of Caesar Boeck, Oslo, during the twenty

years from 1891 to 1910 and who had received no specific treatment whatever have been widely quoted as indicating that in the majority of instances syphilis was cured spontaneously In fact Sowder (1940) believed from his reanalysis of Brusgaard's data, that they tended to exaggerate rather than to minimize the seriousness of syphilis Harrison (1940) on the contrary felt that there were serious limitations to these findings as an indication of what happens when syphilis is not treated with any specific remedy Vonderlehr and Usilton (1938) found that treatment decreases the probability of a disas-

trous outcome in syphilis. Symptomatic central nervous system disease decreases from seventeen in one hundred untreated syphilitic patients to two in one hundred under standard treatment during early syphilis. No patients with cardiovascular syphilis were detected among those well treated and reexamined ten to twenty years after infection (Fig 68 and Kemp and Cochems, 1937) Excellent results (85 per cent cures") obtained with standard treatment in early syphilis reported from patients examined in the three to ten-year observation period were maintained by those patients so treated

and reexamined ten to twenty years after infection The careful study of Padget (1941) based on 551 patients from the Johns Hopkins Clinic, completely reexamined at least five years after the termination of two years of treatment is a monument dedicated to the effectiveness of early adequate treatment and the permanence of results obtained by such therapy Padget found that continuous was superior to intermittent and irregular treatment So many of the patients did so well on little treatment that attention is called to the fact that adequate treatment for all of a large group of patients with early syphilis inevitably results in over-treatment for many A little treatment (7–9 arsenical) in the first three months of treatment is as effective as

From Vonderlehr and Usilton, "The Chance of Acquiring Syphilis and the Frequency of its Disastrous Outcome *Ven. Dis. Inf* Nov 1938

twice as much treatment scattered over the first two years For practical purposes, it was shown that a patient who has done well for five years following the termination of treatment for early syphilis, and at that time presents no evidences of the disease to be found on complete examination, may be discharged from further observation Padget further reemphasized the ominous prognostic significance of early or immediate clinical relapse. Vonderlehr and Usilton (1938) have in tabular form (Fig 69) summarized succinctly the findings from the Cooperative Clinical Group's large material

The Arsphenamines and Neurosyphilis.—It has been insistently suggested that the use of arsphenamine predisposes to neurosyphilis and that methods which rely more upon the patient's physiologic defence such as medication by

mouth yield in the aggregate a milder course and fewer late complications than the hammerings of modern procedure. The best evidence now available indicates that such is not the case.

The longstanding controversy began with Finger who, in 1911, reported 9 per cent of neurorecurrences in his first 500 arsphenamine-treated cases as contrasted with 0.25 per cent in 2000 cases treated with mercury and iodide. This question was answered in the negative by Des Brisay and Stokes when they found that patients untreated, mouth-treated and inadequately treated by modern methods all presented approximately the same incidence of neurosyphilis, namely between 42 and 50 per cent. Guy (1930) has critically reexamined this question. From his citations it appears that neurosyphilis unquestionably became more frequent after the introduction of arsphenamine but that the patients were in general inadequately treated, as in Pette's series from Nonne's clinic. Laster reached the same conclusion from the material of Strumpell's clinic in the years between 1900 and 1922. From their clinical study of 400 cases of neurosyphilis O'Leary and Ropa (1934) could find no substantiation of the idea that arsphenamine predisposes to, or induces the development of neurosyphilis. Mattauschek, in 1924, reported an increase in cerebrospinal syphilis and a stationary curve for dementia paralytica. Marburg showed a shortening of the incubation period in the arsenical-treated group. Hyder found the average incubation time for neurosyphilis among a group infected prior to the introduction of arsphenamine to average fifteen years and a group infected during the arsphenamine era to be seven years. In a well-documented study Kemp and Menninger (1936) found that early inadequate treatment does not increase the incidence of neurosyphilis; with no treatment, neurosyphilis comprises 34.6 per cent of cases, and with early inadequate treatment it comprises 43.4 per cent of cases. They found, however, that the incubation period of clinical neurosyphilis is reduced approximately five years in a group of inadequately treated patients as compared with a group receiving no treatment, i.e., from 19.2 to 13.1 years in males and from 14.9 to 8.7 years in females.

The point to be emphasized in judging the influence of arsphenamine on the prognosis of syphilis with respect to neurosyphilitic involvement is that practically most of the treatment discussed by the foregoing authors ranks as entirely inadequate when judged by present-day standards. The value and efficiency of modern treatment methods in controlling and preventing the development of asymptomatic and late forms of neurosyphilis is now quite thoroughly established and will be discussed in Chapter XX under the Treatment of Neurosyphilis. Merely as an illustration, Moore and Keidel produced the first convincing American evidence that effective combined arsphenamine and mercurial treatment reduces the proportion of patients destined for late neurosyphilitic complication from 26 per cent to the unprecedentedly low proportion of 3 to 5 per cent, by properly directed measures. Such a proportion is so much lower than any accepted statistics of the incidence of neurosyphilis in general, that the improvement in outlook must be accepted as exonerating modern treatment methods from any charge of perverted effect upon the nervous system.

Certain general evidence pointing to a decline in neurosyphilis in the arsphenamine era is appropriate as a defence of the arsphenamines against the charge of inducing neurosyphilitic complications. This material is reviewed by Guy and by Stower, both of whom reach the same conclusion, based upon well-established American figures for dementia paralytica and tabes, that there is a slight but definite decrease in an almost stationary rate and a definite decrease in mortality from these sources. Colonel Harrison has cited likewise convincing figures from British experience (1940).

THE MEANING AND DETERMINATION OF "CURE"

A Definition of "Cure."—Throughout this text the word "cure" has been thrown into quotation marks with the definite purpose of directing attention to it as an expression or verbal form rather than a completely established fact.

The effective definition by the physician of the problem of "cure" and of the methods which must be adopted to work toward it often makes all the difference between a loyal and distrustful patient, and between recovery and failure.

It is well to distinguish, in talking with patients, between clinical and pathologic or radical "cure." The former is defined as a complete relief from symptoms and signs of the disease and ultimate noninfectiousness, with free-

Fig. 70

PRINCIPLES OF PROGNOSIS IN SYPHILIS

I. General Considerations

1 Prognosis is influenced by the type of infection (symptomatic or asymptomatic) infecting organism, race ge and sex of the patient, pregnancy intercurrent infection and disease, and treatment (type, amount)
2. Infection may be asymptomatic throughout its entire course (33–35 per cent, Morgan, 1939) or long latency may precede serious late lesions.
3. The Negro is disposed to develop cardiovascular syphilis, the Whit neurosyphilis.
4. Syphilis may be more serious in the very young and the old.
5. Syphilis is pt t be milder in women and especially in the multipara.
6. A good early reaction (florid secondaries) may protect gainst neurosyphilis, "law of inverse proportions.
7 The serologic reaction is no guide to prognosis.
8. A patient with syphili runs risk in ddition t those of his disease, of predisposition to other diseases (g cancer) and of reactions t treatment.

II. Prognosis of Untreated Syphilis

1 Early Syphilis.—Syphilis shows spontaneous tendency t recovery and disables or kills only a minority of those infected. It may be cured spontaneously
( ) Bruusgaard (1929) showed that 27 9 per cent of patients are spontaneously cured. 22 6 per cent will die of other causes.
14.1 per cent will have only serologic evidence of syphilis.
12 8 per cent will have benign lat syphilis.
12 8 per cent ill have cardiovascular syphilis.
9 5 per cent ill have neurosyphilis. That is t say: One-third of untreated early syphilitics will develop benign or dangerous lat lesion, but two-thirds will pass through lif unharmed.
(b) Sowder (1940) Bruusgaard' results tend to exaggerate the seriousness of the disease rather than t minimize it
(c) Harrison (1940) There are serious limitations t the value of Bruusgaard' data as indication of the prognosis of untreated early syphilis.

II. Prognosis of Treated Syphilis

1 Adequate treatment of early syphilis cures and thus prevents late complications.
( ) W th continuous treatment, begun in the seronegative phase, cure in early syphilis may be obtained in 80 4 per cent of cases. These good results are lasting (Padget, 1940; Vonderlehr and Usilton, 1938) If treatment is delayed to the seropositive primary phase the satisfactory outcome is 64.5 per cent and for secondary syphilis, 81.5 per cent. (Stokes, Usilton et al (CCG) 1934)
(b) Clinical relapse is of grave prognostic import. Seropositive primary has the highest incidence of neurosyphilis and relapse The more arsphenamine, the less relapse (Stokes, 1936 Padget, 1940)
( ) Collected data from the literature show that patients with cardiovascular syphilis, paresis, taboparesis, and tabes dorsalis have rarely received proper treatment in early syphilis (16 of 1208 cases, Harrison, 1940, cf Vonderlehr and Usilton, 1938) Series of well-treated early syphilis result in little or no late syphilis (Padget, 1940)

Fig. 10.—*Continued*

II. Prognosis of Untreated Syphilis	II. Prognosis of Treated Syphilis
(*d*) *The spontaneous involution or curability of syphilis* cannot be depended upon to control infectiousness even if the public health aspects were controllable by quarantine	(*d*) Inadequate treatment of early syphilis predisposes to relapse shortens the incubation period of neurosyphilis, but does not increase the incidence of it. (Kemp and Menninger 1936)
2. **Latent Syphilis** untreated does not always terminate disastrously Cooperative Clinical Group (1934): About 33 per cent satisfactory outcome (freedom from manifestations of syphilis together with spontaneous serologic reversal) Twenty to thirty per cent will show progression or relapse (Clinical relapse especially prone to occur in latent congenital syphilis, Smith, 1933).	2. **Latent Syphilis.**—Treatment yields an ultimate satisfactory outcome in approximately 85 per cent of patients (CCG, 1934).
3. **Late Syphilis** is unpredictable because of the possibility of unrecognizable structural damage There is equilibrium as well as progression element in late latency and late syphilis.	3 **Late Syphilis.**—Treatment of late syphilis does not cure but prolongs life arrest progression and affords symptomatic relief (Grant, 1933; Padget and Moore 1933 CCG, 1930, 1938; Harrison, 1940; Kierland, O'Leary and Vandoren, 1942) Prognosis is an individual matter and depends on type of lesion present, type of treatment and tolerance of treatment. The outlook of patient with fully developed late syphilis (neuro or cardiovascular) has been improved by modern methods of treatment (Fever et)
4 **Untreated Syphilis and Pregnancy.**—Pregnancy may suppress early manifestations. Repeated pregnancies have protective effect. Cooperative Clinical Group (1934) Pregnancy is auxiliary treatment, especially for the colored woman. The pregnant syphilitic woman has less relapses and less clinical progression than the non-pregnant woman. The untreated pregnant syphilitic woman has only one chance in six of bearing live, healthy infant as compared with the normal woman three chances in four	4 **Treated Syphilis and Pregnancy.**—Adequate treatment of syphilis in the pregnant woman assures a living nonsyphilitic child in 91 per cent of the cases (CCG 1934). Treatment of syphilis in the pregnant syphilitic prevents progression and relapse
5. **Life Expectancy of Untreated Syphilis.**—Life expectancy of males with acquired syphilis is shortened from that of the general population from ages 30 to 60 by 17 per cent in the white male and 30 per cent in the colored male (Usilton and Miner 1937).	5. **Massive-dose arsenotherapy** is still experimental, but tentative evaluation of various reports indicates that satisfactory outcome in early syphilis may be expected in about 85 to 95 per cent of the cases (equal to that of routine therapy). (Hyman, 1941 Reynolds, Mohr and Moore, 1942) This treatment is encouraging in late syphilis (Kaplan, 1942) and in congenital and acquired syphilis in children (Levin, Hoffman and Koransky 1942).

dom throughout life from complications and recurrence under proper observation and control Pathologic or radical cure is defined as the complete extirpation of the infection the destruction of every one of the invading spirochetes, so that treatment may be dropped and the patient comport himself as though he had never had the disease. Clinical cure, taking syphilis in all aspects, and year in and year out, can be brought about in 80 to 100 per cent of patients who will cooperate in treatment and observation Pathologic or radical "cure" is still on a basis of theory rather than finally established fact.

"Cure" *versus* Arrest.— Cure in anything approximating the strict sense is discussable only for early syphilis Patients who have developed the late manifestations of the disease are usually the better for an explanation of the distinction between "cure" and symptomatic arrest. In a sense clinical "cure" is arrest, but for the patient who has sustained residual damage, arrest can be made clearer by pointing out to him the fact that restoration to normal cannot be expected where there has been permanent destruction of vital tissue by the disease.

Serological and Symptomatic "Cure. —*The former term means, of course,* permanent blood serological negativity with a permanently negative spinal fluid to the four tests. It goes without saying that this condition in the light of previous discussion is by no means equivalent to clinical "cure. Progression of the infection under a mask of complete serological negativity is in fact, especially frequent in the gravest aspects of the disease such as cardiovascular and neurosyphilis The patient determined to know the results of his "test" will more than once need to have this situation explained to him. Symptomatic "cure" means nothing more than relief from the presenting symptoms It is the *beau ideal* of snapshot and opportunistic syphilology and the *bête noir* of the conscientious syphilotherapist. In old age it has its place and it may be offered to the "wreck" whose hope of better things has gone the road of negligence or mismanagement but it has little place in the syphilotherapy of the active years of life In fact, it is a modern axiom that treatment of the syphilitic patient should invariably be carried beyond the point of symptomatic "cure" for in no other way can even a semblance of permanence be expected.

"Cure" in Early Syphilis.—Unfortunately upon the issue of individual cure in early syphilis, it is impossible to speak with absolute definiteness and assurance. Without question hope and wishful thinking will need constant and determined differentiation from certainty in this field for perhaps another 25 years. In two figures (71 and 72) we have attempted to summarize first a classification of evidence and alleged evidence relative to the curability of syphilis in its present-day status and secondly what might be used as a guide to the ritual of active and presumptive criteria and tests which should underlie the assertion that a given patient is "cured" It will be noted that the clinical criteria begin with statements regarding standards of treatment which the most critical of recent observers must must be incorporated into any estimate of the status of a given case with reference to "cure." The details of the treatment method comprehended under these heads are discussed in Chapter XIV Points 6 and 7 on the clinical side, emphasize the necessity for physical examination, for which no roentgenological or serological procedure can ever be a substitute. Point 8 recognizes the completeness of asymptomatic latency in women. Point 9 is based on the current belief discussed later that two negative examinations of the spinal fluid a year or two apart, after treatment has been completely suspended justify belief that the central nervous system

Fig. 71

A CLASSIFICATION OF "EVIDENCE" RELATIVE TO THE "CURABILITY" OF SYPHILIS

Pro.	Con.
1. Undoubted curability in animals.	1. Lifelong infection if untreated in animals.
2. Reduction in the incidence of the disease in populations.	2. Examples in man of asymptomatic course and prolonged latency (up to fifty to sixty years)
3. Reduction of incidence of certain complications (paresis)	3. No absolutely valid, single or combined proof applicable in life.
4. Results of blood serological surveys and recheck of treated cases.	4. Known clinical progress in spite of serological negativity in blood and spinal fluid. a. Clinical activity in spite of provocative negativity
5. Results of complete reexaminations, physical, serological, neurological (including CSF) cardiovascular of treated cases.	5. Too short duration of observed cases.
6. Occasional negative autopsies of treated cases (Fig. 436)	6. Too few autopsy proofs based on microscopical study of adequately treated syphilis in man
7. Existence of spontaneous cures.	7. Evidence that therapeutic and prophylactic agents are bacteriostatic not bactericidal (Kolle and Evers with bismuth. Turbelle on prophylactics. Eagle 1938–1939)
8. Existence of immunity to reinfection independent of cure. Gives hope of cure which does not require reinfection to prove it.	8. Small proportion of spontaneous cures.
9. The apparent ready response (symptomatic) to treatment	9. Kolle's concept of the symptomatic carrier
10. Evidence provided by reinfection (proved)	10. Uncertain status of reinfection as proof of cure in the light of newer knowledge of superinfection.
11. Assertion and hope	11. Ubiquity and frequency of various forms of relapse and their confusion with reinfection. (See Reinfection after intensive arsenotherapy.)
	12. The contentions of Warthin based on spirochetal findings postmortem.
	13. Time still too short to determine cure (not less than fifty years required)
	14. Increasing difficulty of demonstrating serological negativity with increasingly sensitive technics.
	15. Birth of syphilitic children to completely asymptomatic mothers.
	16. Uncertainty of tissue transplant as proof of cure (Chesney and Kemp, Haleeby and Greenbaum, Worms and Schultz, Lake and Bryant) (*Establishment of the lymphatic reservoir conception in man.*)

is permanently free from involvement, a statement to which there are inevitable exceptions. Point 10 setting reinfection after a number of years as clinical evidence of "cure," will be subject to criticism in subsequent paragraphs. The crux of the whole problem and the concession that must be made to the

Fig 7d.

ITEMS IN THE PROOF ACTUAL OR PRESUMPTIVE, OF "CURE" IN SYPHILIS

Clinical	Laboratory
1 Early beginning of treatment (seronegative primary or first few weeks of secondary period)	1 No suggestion of temporary positive in an initial seronegative case.
2 Vigorous nd prolonged treatment (Moore and Kemp, Hoffmann, Sezary Chargin and Stone Harrison)	2 A normal rat of reduction of positive blood serological tests t negative (not too rapid) Preferably controlled by quantitative procedure.
3. Effective se of arsphenamine (Stokes, Cole et al)	3 No clears slowly and weak positives in any subsequent tests.
4. Continuous treatment (Moore nd Kemp, Stokes and Becker Stokes, Miller and Beerman, Am. Coop. Clinical Studies)	4 N serological relapses in series of tests over period of years.
5. Absence of all subjective symptoms.	5 T test procedures used in each case (Wassermann and precipit tion, including "presumptive type")
6 Absence of objective physically detectable lesions, especially heart and nervous system.	6. Negative provocative and serological test series t outset of new courses (see p 103) The negative provocative test is not reliable evidence of cure.
7 Negative cardiovascular stripe t roentgen-ray examination and fluoroscopy	7 The spinal fluid cell counts and total protein absolutely normal in blood-free specimens.
8. In women, the nonappearance of syphilis in children unprotected by treatment	8. Negative lymph node and tissue (chancre scar) inoculations into animals (followed t or more generations)
9. T or more spinal fluid examinations negative interval one year or over	9 Autopsy complete, controlled by microscopical and animal inoculation studies.
10. Occurrence of reinfection after the period of relapse and with fully satisfied criteria (Hoffmann)	
11 Repeatedly negative complet physical reexaminations over a period of as many years as possible, up t ld Thus t nclude ey and ear	

THE RADICAL OR COMPLETE CURABILITY OF SYPHILIS IN MAN REMAINS TO BE PROVED THE CONTROL OF THE DISEASE BY PREVENTION OF INFECTION IS POSSIBLE

insoluble elements in the riddle of syphilis in man are the lifelong periodical examination and the necessity for an autopsy of almost unheard-of completeness as a demonstration of "cure." The patient clamoring for radical assurances usually subsides into silence when the practical valuelessness of the indispensable autopsy criterion for his peace of mind is pointed out.

The intensely human and inevitably fallible element in the determination of cure are nowhere better illustrated than in the evaluation of the older standard treatment and the newer foreshortened intensive therapy of early syphilis. There is a curious and interesting uniformity to be pointed out in the percentages of good result not alone in syphilis by a variety of methods of treatment, but even in the treatment of other diseases by newer methods — in the case of gonorrhea. It seems that expectancy of cure by modern chemotherapy has a tendency to approximate 80 to 90 per cent of patients treated by empirically or experimentally determined standards. This suggests that a residue of 10 to 20 per cent of human beings infected with these diseases will, for various reasons, not as yet clearly understood, fail of cure despite the employment of the most intensive and effective methods. It is at this "inveterate residue" against which, in syphilis at least, much of the prolongation and intensification of therapy is being directed. It is clearly recognized that far more moderate standards could secure an 80 per cent "satisfactory" result. In this zone of the inveterate residue the stiffened criteria of cure must be sedulously applied lest wishful thinking and the inevitable human desire to prove the value of an investigated or favored method, warp the judgment of the investigator. These remarks apply specifically to the use of such criteria as reinfection in determining the curability of the disease. The differentiation of relapse and reinfection which is, of course, essential to the value of reinfection as a criterion of cure can be loosely carried through, with strong and visible desire to increase the number of reinfections in order to prove more cures. (Schoch) The conservative reaction of Leifer, Chargin, and Hyman, and of Elliott, Baehr, Shaffer, Usher and Lough and Thomas and Wexler is to be commended. They have refused to allow the slightest trace of wishful thinking to enter into their estimate of the effectiveness of the 5-day drip and multiple injection technics they employ by calling even plausible (though not "air-tight") reinfections anything but relapse.

The group disposed to relax reinfection criteria (Moore, editorial 1945) points out, however very properly that changes induced in the immunologic responses of syphilitic disease by rapid intensive treatment, may prevent the development of immunity and hence increase the probability and possibility of reinfection. The most that can be said at this moment is that the experienced investigator knowing the many factors involved, and knowing the inevitable human tendency to bend evidence towards the proof of a desired conclusion, will avoid temperamental reactions, wishful thinking, belief and hopes in his appraisal of the cold evidence for cure. Reinfection, especially in the light of what is known experimentally about superinfection, should still be examined most critically and available evidence should be classified according to grade of presumption it provides, whether or not we are "convinced of (her) promiscuity!"

The classification of evidence relative to the curability of syphilis at once discloses (Figs. 71–72), by the deadly parallel column method, the slenderness of the cord by which our hope seeks to mount to its fulfillment. On the clinical side the undoubted curability of syphilis in animals, the hope extended by the work of Chesney that reinfection is not indispensable to proof of cure and the results of complete examination of patients up to as long as twenty years after infection provide the chief substantial element. Figure 436 contains a summary of completely negative autopsied, treated case, but the number of such cases is all too few to carry much weight as evidence and the difficulties and rapid changes taking place in the technic of tissue examination, particularly under the studies of Warthin, have invalidated at least a part of such evidence as already exists. Here again must be quoted the highly significant statement of this lifelong *Spirochaetenforscher* made before the British Medical Association in 1929 that he has never seen a completely conducted autopsy which failed to reveal evidence of latent syphilis in syphilitic persons, or substantiated any claim to "cure. Warthin conceded, however that the five-year treatment ideal had not yet passed in review before his autopsy methods.

It should be emphasized at this point that much of the evidence adduced in favor of the curability of syphilis from the clinical side rests upon wholly inadequate clinical evidence. The tendency to rest upon a preconceived notion of the amount of treatment necessary for a cure in deciding whether or not a cure has actually been accomplished, may be a very serious one. It is equally impossible to depend upon any single test or group of tests applied at any given time for an absolute proof of cure. In discussing the mechanism and frequency of relapse, examples will be cited which will illustrate both these problems. The physician tends too readily to think in terms of courses and to rest his case with the inevitably arbitrary statement: "There, you've had enough. This relapsing test or finding must be false" instead of recognizing the ubiquity and, in certain cases, the inevitability of relapse

Serological Tests in "Cure"—The use of serological tests in determining the outcome of syphilis has been sufficiently discussed. It should only be

emphasized here that the instrument which will almost undoubtedly be invoked in the coming five to ten years, namely an ultrasensitive serological procedure for the detection of the faintest traces of positive tendency in the serum of the treated person, is a double-edged procedure which, as yet, at least, rests on an imperfectly developed interpretation of the actual meaning of the presence of syphilitic reagin in the blood with respect to activity arrest or "cure Clinically however it may be stated that no series of negatives in any form of serological test on blood or spinal fluid can carry absolute weight with respect to cure" in our present knowledge of the situation.

Tissue Transplantation in "Cure" Evaluation.—In the first edition of this text it was suggested that rabbit inoculation might be used to take advantage of the possible existence of lymph node reservoir in man t demonstrate the presence of *Spirochaeta pallida* or its absence, in supposedly cured cases. More recent work seems to make this method appear of doubtful reliability

Chesney nd Kemp pplied this method in 8 patients, obtaining negative results by lymph node inoculation after treatment and subsequent observation periods ranging from one to four and three-fourths years Saleeby and Greenbaum elaborated and extended the method, reporting on 89 patients with cute and chronic untreated syphilis from whom inguinal lymph nodes were removed and reporting that the condition of the rabbit, particularly ith respect to feeding, was vital in these experiments. In the 23 results which they were able to interpret from this series, it was found that the nodes of patients with untreated acute early syphilis always contained *Spirochaeta pallida* but that this was true in only about 43 per cent of patients with untreated chronic syphilis. Of sixteen skin transplants from patients in all stages of syphilis, two gave positive results; two leukoplakic transplants gave negative results. They concluded that human node transplants cannot be used as means of determining cure in syphilis since *Spirochaeta pallida* disappears from these nodes spontaneously in many untreated and uncured cases. If they are not invariably present in untreated cases, their absence in treated cases is of no value so far as criterion of cure is concerned. These uthors pointed out that the disappearance of the secondary eruption in syphilis does not always mean destruction *in situ* of all spirochetes causing that eruption. The finding of residual spirochetes in two instances out of sixteen skin transplant studies made, suggested to them the reason for the development of gummas in later li They found that persistently enlarged lymph nodes in patients with syphilis are no indication of the presence or absence of *Spirochaeta pallida* in such nodes. Zieler and Hämel in 7 patients adopted an immunological method of testing the possible presence of latent syphilitic infection in the rabbit inoculated from lymph node tissue. The method employed was the cross-inoculation technic of Kolle using the Truffi strain, and from the very high proportion of infections which they secured in their rabbits they concluded that they had not become carriers of latent syphilis by virtue of their inoculation with human lymph node tissue and that the patients were, therefore, in all probability cured. These results must, of course, be subject to Saleeby and Greenbaum criticism of lymph node transplant as procedure. Use of the chancre scar for determining the survival of residual infection has some interesting possibilities based upon the observations of Sandmann, Pasini, E Hoffmann and others

Tissue inoculation methods have the apparently inescapable drawback of requiring the cooperation of a laboratory for experimental syphilis which, unless established under centralized control and facilities, is practically not accessible to more than a handful of clinics in the entire world.

Reinfection as a Criterion of "Cure."—In view of what has just been said regarding a tendency to relax criteria of reinfection in order to meet certain special immunologic conditions perhaps prevailing under intensive treatment for early syphilis and thus increase the justified evidence for cure we feel it doubly desirable to re-state the three grades of strictness (Fig 73) by which the validity of reinfection may be judged That the indisputable group embodies the strictest criteria yet promulgated does not for a moment *ipso facto* invalidate either the criteria or the propriety of using them in appraising the status of an alleged reinfection. If reinfection is to be more freely diag-

Fig. 72.

CRITERIA OF REINFECTION ARRANGED IN THREE GRADES OF STRICTNESS[1]

Grade I Indisputable.	Grade II: Probable	Grade III Possible.
1 First infection proved by blood Wassermann reaction or darkfield.	1 Indisputable first infection.	1 Indisputable first infection.
2. Negative physical examination t years after treatment.		
3. Negative blood Wassermann for one year after treatment.	2. Clinically and serologically negative for one year after treatment.	
4 Negative spinal fluid at end of treatment.		
5. No relapse between the two infections.		
6. Definite exposure history for second infection.		
7 Infectious source for second infection		
8. Normal incubation period for second chancre (seven to forty days)		
9. Second chancre in different site and lymph drainage from first.	3. Second chancre in (a) different site (b) different lymph drainage from first.	2 Second chancre different site from first
10. No activity at site of first chancre.	4. No signs of activity at site of first chancre.	3. Second chancre characteristic appearance
11. Positive darkfield, second chancre.	5. Positive darkfield on second chancre.	4 Positive darkfield second chancre
12. Satellite adenopathy present, second chancre.	6. Satellite adenopathy present, second chancre	
13. Blood Wassermann reaction of second infection, negative at start, must change to positive.	7 If blood Wassermann reaction becomes positive under observation or—	
14 Secondary eruption must appear not less than t enty days after first chancre	8. If secondary eruption ppears at the proper interval, laxity ill be allowed in items 2, 3b, and 6.	
15. Treatment of first infection must approximate 20 arsphenamine injections and 20 bismuth or mercury injections		5. Second chancre must appear at an interval after antisyphilitic treatment
16 Time interval between first and second infection must be 2 years or more.		
17 Competent observation must be had in both infections.		

[1] From Stokes, Cole, Moore, O'Leary Parran and Wile Ven. Dis. Infor 12:55–68, February 20 1931

nosed with or without intent to prove more cures by intensive technics, the grade of proof is still a matter of critical interest and places the use of "probable" and possible classifications in the same category with the use of prolonged serologic negativity and absence of clinical signs in the general evaluation of "cure." Infallibility can only be claimed for a procedure and for cases which have satisfied the strictest conceivable requirements. Such cases, under the stimulus of this challenge, are increasing in number (Cannon, 1933 Klauder and Butterworth 1934 Tobias, 1934 Kopp and Solomon, 1930 Hahn 1941 Allison, 1942) and this tendency should be encouraged instead of derided by those who have something to prove

The question was critically reviewed on the basis of two groups of material in 1930, the first by Stokes, Schoch and Ireland from the material of the Syphilis Clinic of the University of Pennsylvania, nd the second from the material of the Cooperative Clinical Group for Retrospective Syph lis Investigation a presented by Stokes, Cole, Moore O'Leary Parran and Wile t the International Dermatological Congress in Copenhagen. It will suffice here, since the discussion of reinfection should technically accompany that of relapse, which it so much resembles and from which it is with such difficulty differentiated, that the criteria of reinfection be reviewed (Fig. 73). The conclusions dra from these two studies and involving comparison of our own experience, that of 40 infections occurring in the Cooperative Clinical Group and 237 reinfections collected from the literature by Halley and Wasserman, plus number of critical reviews, including those of Bernard, Hell, Hudelo and Rabut and others may be summarized as follows: the evidence collected tends to indicat that many reinfections are vitiated as clinical evidence by their occurrence within the time period after the first infection and ith the amount of treat ment for the first infection hich characterizes from 80 to 93 per cent of relapses. The weaknesses of existing material on reinfection with respect t historical detail, adenopathy scar and site of the chancre, examination of the spinal fluid and adequate physical examination, are very striking. On the basis of the criteria grouped as indisputable, probable and possible reinfections, it appears that there are no indisputable reinfections the evidence for which conforms to every requirement, about 116 conform t moderately rigid standard and 120 conform to an average standard which in our ow opinion is too lax to provide for the confusion elements of relapse morphology It is suggested that the highest ideal of syphilological reporting would be the presentation of cases of airtight reinfection.

THERE IS NO PROOF OF "CURE" EXCEPT OBSERVATION

Time and Observational Control.—"Observation throughout life," a previously widely held ideal for the cured syphilitic, has been subjected to modification by several critical analyses, including those of Stokes and Usilton and Vonderlehr and Usilton based on Cooperative Clinical Group data, and Padget (1940) based on the material at the Johns Hopkins Hospital Clinic The first-named authors stated their findings as follows

The possibility of unearthing significant data in period of observation up to ten years after the cessation of treatment is from 8 to 23 chances in 100. For ideal continuous and inter mittent treatment respectively it approximates 8 and 10 chances in hundred. Hence it seems that for those ho demand absolute assurance for those whose timidity makes repeated serologic and clinical examinations the only escape from syphilophobia; for those who have been given inadequat or desultory treatment in the first year of the infection, and for women who may or have become pregnant, indefinitely prolonged or repeated observation is necessary On the other hand, for those who can accept reasonable and in fact high probability of cure after strict adherence to an effective and especially to continuous treatment regimen in the first two years, and hose lives will be shadowed or disturbed by the exactions of observation, five years of probation after treatment ends is sufficient. I special situations such as definite relapsing tendencies, observable during treatment, or marked predisposition to serious types of nvolvement early in the disease special consideration may be necessary All patients should be told that cardiovascular examination should be performed by competent observer in the five- t ten-year period because of the yet unevaluated status of this group of complications, and

that in the case of women contemplating conception the status should be reviewed, and in all probability the pregnant woman who has once had syphilis, should be treated for the disease throughout each pregnancy. Thus, potential cardiovascular disease and the transmission of syphilis to the unborn child remain the two intrinsic justifications for prolonged and repeated observation after prompt and adequate treatment for early syphilis.

To this statement Vonderlehr and Usilton's observations added the important fact that no significant difference between the incidence of satisfactory results among 504 patients followed from three to ten years, appeared in comparison with a partly overlapping group of 61 patients who had been followed from ten to twenty years. Padget's material, which perhaps more closely approximates the cross section of the performance of a first-class clinic found that no distinction was required between 278 patients who were followed for five to ten years, and 273 patients who were followed for ten years or more. Not one of the 170 patients who had attained "cure" five years after treatment was suspended, was found to have manifested progression or relapse at re-examination ten or more years after the original treatment, irrespective of its type or amount. This statement is obviously of great significance to public health administrators, life insurance companies, and various Federal and state agencies which offer insurance and pension benefits.

A guide which we believe effective for the re-examination of treated syphilitics for the question of "cure" is that given in Chapter II (Figs. 12 and 13). It should be emphasized that cardiologic expertness and particularly the adequate interpretation of the fluoroscopic picture may be of differential importance.

It appears, then, that the really sovereign tests of "cure" are time and observation. When after five years, the patient who has satisfied the serological requirements of the older writers by a negative blood and spinal fluid slowly develops signs of syphilitic vascular disease one learns that there are no infallibilities in modern therapeutic syphilology.

CHAPTER VI

THE HEAVY METALS AND THE IODIDES

Principles of Action of the Heavy Metals Reviewed.—It appears that the arsphenamines occupy one extreme of a mechanism combining both spirillicidal and resistance-building properties, with mercury at the other extreme and bismuth as an intermediate all three being united presumably by an underlying chemotherapeutic mechanism involving responses in the reticulo-endothelial system combinations of tissue protein with the active drugs to form spirillicidal agents and linkage with the glutathione oxidation mechanism of the living cell by which these parasitotropic substances act or by a direct spirillicidal action (Eagle 1938) It has long been evident that storage and rate of elimination in their reciprocal relations have an immense influence on the chemotherapeutic efficiency of the entire series of antisyphilitic drugs. As Hanzlik has stated in discussion, the amounts of mercury for example retained in the body to exert their effect upon the infection must be of the order of hundreds of thousands if not millionths of 1 per cent. The scientific evaluation of the action of heavy metals has been delayed for centuries to await the development of chemical methods for the detection of minute amounts present in large residues of organic material. Route vehicle salt and site are almost as vital to the clinical effects of the heavy metals in the treatment of syphilis as the metallic ions themselves.

Important Considerations in the Use of the Intramuscular Route for Heavy Metals.—Intramuscular medication, in spite of recent interest in oral bismuth therapy seems likely to replace almost entirely the simpler technics and a comprehension of the fundamental principles involved in this way of giving these drugs becomes doubly important. When a physician injects intramuscularly or subcutaneously a preparation containing a heavy metal, he brings into play eight factors in addition to the actual quantity of the metal introduced as follows

1 The solubility of the drug in the vehicle (Fig 74)

2 The solubility of both in tissue fluids

3 The local reaction aroused including reaction to the vehicle, reaction to the deposited or perhaps precipitated drug, and reaction to the drug in solution

4 Influence of the site of injection

5 Rate of absorption of the drug from the injection site

6 Accumulation of the drug at the injection site.

7 Late changes, produced by a series, as distinguished from a single injection, including possible altered absorptive capacity on the part of the tissue and altered elimination by the body (retardation in the case of Bi)

8 Toxicity effects which are irremediable if overdosage or overaccumulation has been allowed to occur

The eight named factors outrank, in the opinion of Hanzlik, for example even the quantity of the actual metallic principle introduced per injection. The ideal drug for various occasions will vary greatly with so commonplace a

consideration as the frequency with which the patient can come for treatment or the length of time he will continue it or the duration of the rest interval which circumstances will demand upon the completion of a course. Local

Fig. 71

COMPARATIVE RESUME OF BEHAVIOR OF HEAVY METALS WITH RESPECT TO SOLUBILITY

Soluble in water or propylene glycol	Water (or glucose) suspended (insoluble)	Oil-soluble	Oil-suspended (insoluble)
1. Simpler salts of heavy metals.	1. Only bismuth metal or salt practicable	1. Oil bismuth salts.	1. Heavy metals, simple and double salts.
2. More pain (local necrosis and inflammation)	2. Less than soluble salts.	2. Little or no pain.	2. Late local pain and induration.
3. Most rapid absorption.	3. Slow regular absorption.	3. Mild rapid absorption, regular and complete	3. Slow irregular absorption.
4. Frequent injection (daily to 3 times weekly)	4. Once weekly	4. Once or twice weekly	4. Infrequent injection (weekly)
5. Rapid action.	5. Fairly rapid action.	5. Moderately rapid action	5. Slow erratic action in some, good in others. Often powerful effects.
6. Transient effect	6. Moderately prolonged effect.	6. Moderately prolonged effect	6. Prolonged effect.
7. No encapsulation or sterile abscess tendency	7. Extensive deposition. Metals may encapsulate	7. Moderate deposition. No encapsulation.	7. Encapsulation occasional, tend to form soaps and deposit calcium. Foreign body reactions.
8. Toxicity high but controlled.	8. Toxicity low	8. Toxicity low	8. Toxicity unexpected and often high due to difficulty in control (accumulation, erratic absorption)
9. Rapid elimination.	9. Good but more prolonged elimination.	9. Rapid elimination.	9. Prolonged elimination
10. Little accumulation.	10. Marked accumulation in metals, less in salts.	10. Little accumulation.	10. Very cumulative.
11. Quick local and sharp transient excretory mechanism irritations.	11. No excessive irritation or toxicity	11. No excessive irritation or toxicity	11. Late chronic intoxications.

reaction will determine the patient's willingness to continue treatment quite as much as it will the absorption of the drug and local reaction will be determined quite as much by the vehicle as by the drug itself

The Local Reaction.—Lomholt has suggested that a moderately pronounced local reaction *is an advantage in securing rapid and effective absorption* rather than the reverse and has protested the disposition of manufacturers to select preparations too exclusively on their nonreaction-producing qualities. It seems not improbable that some of the nonspecific action of intramuscularly injected heavy metals may be comparable to that of sulphur, turpentine and *so forth*, *in arousing the defence mechanism through nonspecific inflammatory* effect as well as through the action of the injected drug. In this way perhaps calomel, the famous local-reaction producer of the mercurial era, in spite of its tremendously slow absorption and cumulative effect, gained some of its reputation as a powerful antisyphilitic remedy. Local reaction is influenced not only by the vehicle, the water-soluble preparations producing the most reaction immediately, and the oil-soluble preparations late, but it is affected by the degree of subdivision of the suspended drug.

Lomholt showed, in the case of bismuth oxychloride, that the smaller the particles the more *rapid the absorption and the greater the pain produced, while the larger particles produced little* local effect. An optimum size of 3 to 5 μ proved a satisfactory compromise between good rate of absorption and minimal local pain production. This effect has also been observed with calomel and potassium bismuth tartrate in oil, English calomel having long been given preference, presumably because of its fine state of division, and certain lots of insoluble suspension sometimes giving rise to much more marked local reaction and even to abscess formation, while other lots *of the same drug identical in chemical composition are well tolerated.*

Distribution of the Drug *In Situ*.—The aqueous suspensions of insoluble preparations show a much wider distribution than the heavier oil suspensions of very finely divided powders. These latter, as Lomholt has noted, form *sharply localized deposits which often undergo rapid encapsulation.* **Massage becomes consequently a particularly important part of the technic of intramuscular injection, especially of insoluble preparations, for it tends to widen the area of absorption and prevent encapsulation and excessively severe local necrosis, with pain, breakdown or abscess formation.**

Grabast has specially studied the comparative reactions of intramuscularly injected preparations, including the arsphenamines and heavy metals. He emphasizes the fact that every intramuscular injection leaves a scar. Most very irritating preparations, such as the arsphenamine group, produce abscesses whose contents are very slowly absorbed, and mercurial and bismuth compounds producing such local reactions only in less degree. He rates mercury thiobenzoate, benzoate, and cyanide as producing the most rapidly absorbed tissue changes and sodium bismuth thioglycolate as a water-soluble and tissue-fluid-soluble preparation as producing the least local reaction of all. Whether in view of Lomholt's opinion just cited, this is an advantage or not would seem to deserve further study.

Absorption from Injection Site.—The absorption of heavy metals from *injection sites depends apparently upon solubility in tissue fluids rather than* on phagocytosis. Sproull and Lehman (1042) for example, found that intramuscular absorption at comparable hydrogen ion concentrations is a function of the chemical stability. They also found that in general absorption (after oral administration) is also a function of the stability of the preparation in the presence of chloride or phosphate. *In general it is accepted that the heavy* metal goes into an albuminoid combination, though this can hardly be invariably true if Lomholt's observation on the elimination of mercury salicylate as such is correct. The bismuth protein combination has been given a special name by Levaditi (bismoxyl) and is assumed to be a highly spirocheticidal substance of which only minute amounts *are necessary for physiologic action*

The Local Depot.—It is apparent from this summary that the local depot produced by the deep subcutaneous or intramuscular injection particularly of oil-suspended insoluble heavy-metal preparations and of arsenicals which produce a high degree of local necrosis, abscess formation and encapsulation becomes an extremely important element in their therapeutic effect. The sharp difference between intramuscular and subcutaneous deposit of the injected material is well illustrated by the findings of Von Oettingen, Todd and Sollmann, who *in a study of bismuth hydroxide found that 30* per cent of the injected material was unabsorbed after thirty days following intramuscular injection but even after seventy days following subcutaneous administration, 90 per cent of the injected bismuth could be recovered from the site of injection (*vide* Anwyl Davies, who recommends the deep subcutaneous use of bismuth) An additional peculiarity of oil-suspended preparations, likewise of considerable importance is their tendency to form calcium soaps at the site of injection followed occasionally by quite extensive calcification which is particularly confusing in the attempt to identify the presence of unabsorbed drugs by roentgen-ray

An additional consideration of import nce in intramuscular injection, from the investigative standpoint, is the striking difference in the rate of bsorption of heavy metals from deposits in different animals. According to Von Oettingen, Todd and Sollmann, the absorption of ter soluble bismuth citrate in rabbit is much slower than in cats, the ratio being as high as 1: 4 This, with the greater tolerance of the rabbit for bismuth, as demonstrated by Kambel, makes it appear that the rabbit is not particularly satisfactory animal for the study of heavy-metal effects in the treatment of syphilis

Muscle Use as Affecting Absorption.—Gruhzit has demonstrated with excellent microphotographs the greatly increased grade of absorption which takes place when the drug is injected into an active muscle. This is a sufficient reason for the preference of the gluteal muscles, constantly involved in walking and massaged by sitting in comparison with the infraspinatus beneath the scapula, for example which is sometimes used as a site in shoulder injections.

Shaking the Suspension as Affecting Absorption.—This has been investigated by Cole and associates who have pointed out that even with fairly vigorous shaking the dose of heavy metal delivered from the top of a bottle containing a hand-shaken suspension, even though beads were used in agitating the preparation, may be as little as one third of the normal or supposed amount. In the case of bismuth preparations the variation as a result of this factor was least with a bismuth subsalicylate cream The mechanical shaking method has given us much better results.

Absorption by Container—A gelatin capsule has been shown in one preparation to be responsible for the taking up or fixation of a good part of the mercury bichloride in the contained fat suspension.

The foregoing emphasis on the storage of heavy metals at the injection site must not be allowed to obscure the equally great importance of the internal storage of the drugs concerned in various organs of the body This will be taken up separately for bismuth and mercury

BISMUTH

General Considerations the Replacement of Mercury by Bismuth.—Just as the spirillicidal therapy of syphilis was transformed by the synthesis and

application of the arsphenamines, so the heavy-metal therapy of syphilis has sustained its miracle within the past two decades in the practical substitution of bismuth for mercury throughout the larger part of the syphilological field. This change, which seems comparable in the opinion of many observers to the introduction of the arsphenamines, is the product of two peculiarities of the new drug: first, its superiority in spirillicidal effect as compared with mercury, though still inferior to that of the arsphenamines; and secondly, its greatly lessened toxicity as compared with mercury. The latter consideration especially has removed from the minds of the majority of observers the objection to prolonged continuous treatment with the arsphenamines and heavy metals. These considerations easily outweigh the inconveniences and lack of flexibility, such as they are, of a single-route drug. Bismuth thus finds its place particularly easily in an era dominated by the intravenous administration of the arsphenamines.

Historical Considerations Concerning Bismuth.—Bismuth, in contrast with mercury, is indeed a therapeutic newcome. Its first therapeutic use was apparently by Odier in 1786, the first animal experimental work was carried through by Orfila in 1842, the phosphorus-like injuries to heart, kidneys and liver were studied by Lebedeff, the distribution of the drug in the tissues by Dubinsky in 1870, and bismuth was demonstrated microscopically in the epithelial cells of the mouth in the same year. Kunkel early demonstrated the point already mentioned regarding the marked *difference in behavior of the drug in different animals. While it is generally accepted that Balzer* in 1889 first introduced the treatment of syphilis with bismuth, Levaditi points out that Masucci had already employed the drug in secondary and tertiary manifestations and Reynolds had recommended it in syphilitic suppurative processes. The use of the highly toxic bismuth ammonium citrate was apparently responsible for Balzer's failure to popularize the use of bismuth in the treatment of syphilis and the drug suffered a prolonged obscurity until Sauton and Robert, in 1916, studied the action of the tartro-bismuthate on chicken spirillosis and, finding that the sodium salt exercises a bactericidal action on *Spirochaeta gallinarum*, suggested that it might be useful in the treatment of syphilis. Following Sauton's death in the War, Sazerac revived his studies and, with Levaditi, in 1921 announced that the tartro-bismuthate of potassium and sodium has a decided curative effect on experimental syphilis in rabbits. In the following year (1922) after tests on man, they stated that bismuth is comparable to the best antisyphilitic remedies and rated its effectiveness as greater than mercury though less than the more active arsenical drugs. This clinical testing of the preparation was then taken up more elaborately by Fournier and Guénot, who announced, following the treatment of 200 cases, that the *Spirochaeta pallida* disappeared rapidly and the Wassermann reaction became negative in primary and secondary cases although it was comparatively little altered in late syphilitic disease. Sazerac and Levaditi and Fournier and Guénot worked with the comparatively unsatisfactory insolubles, including the citrate, subgallate and tartro-bismuthate. It is an interesting commentary on the narrow escapes from glory that give the human touch to the scientific field, that Kolle and Ritz had worked with intravenous injections of colloidal bismuth in the treatment of *Spirochaeta cuniculi* infections in rabbits, in 1919, and found them to be ineffective.

The grave toxicity of bismuth by intravenous injection was first shown by Sazerac and Levaditi and substantiated by Klauder and by Sollmann and Seifter (1932). Klauder further showed the inactivity of bismuth by inunction. With these studies as a base, the investigative work and literature involving bismuth has grown to colossal proportions, completely dwarfing both in quantity and scientific value the entire tradition of mercury, both clinical and experimental. The world-wide dominance of the arsphenamines has not escaped the critical attack of bismuth enthusiasts and there were clinics, such as that of the Hôpital Cochin in Paris, in which not a single injection of an arsenical had been given for more than ten years after the advent of bismuth (Fournier, Schwartz).

Spirillicidal Action of Bismuth.—Depending on the dose type of preparation (soluble insoluble) and route of administration (injection or oral administration) various studies have shown that the rate of disappearance of spirochetes from the early lesions of syphilis in man varies from about twenty four hours to about eighteen days while neoarsphenamine causes spirochetes to disappear from similar lesions in less than twenty four hours to more than six days Pronounced though the spirocheticidal properties of the drug certainly are, it must be repeated that as shown by this comparison they are not great enough to justify the complete substitution of the drug for the arsphenamines in securing the immediate sterilization of the patient, for public health if for no other considerations.

The Mode of Action of Bismuth.—The mechanism of action of bismuth is not definitely settled. It has been suggested that it functions as a catalyst for spirochetolysis *in vivo* (Levaditi *et al.*, 1924–1934) that it is inactive *per se* but combines with tissue derivatives, influenced by glutathione to form actively spirocheticidal compounds ("Bismoxyl" Levaditi *et al* 1924–1937) that it merely inhibits the multiplication of spirochetes (spirochetastasis) (Kolle and Evers, 1926) and that it is directly spirocheticidal (Giemsa, 1922 Kadisch, 1926 Kolmer 1926 Eagle 1938–1939 Kolmer Kast and Rule 1940)

Kolle and Evers have maintained that the action of bismuth is not spirillicidal but that the drug acts rather as an inhibitor of spirochete reproduction.

This view is based upon Kolle demonstration of the inhibition of chancre development in rabbits by depots or plugs" of bismuth injected int the tissues of the ear So long as the "plug as allowed to remain in place no primary lesion developed, but as soon as it as removed by excision the development of the chancre followed at intervals of from two t four months, approximately the normal time Worms accomplished the same effect in rabbits with intravenous injections of bismuth preparation (Balbern)

Eagle s recent findings partially anticipated by Giemsa s observations with higher concentrations of Bismutyl, by Kadisch (1926) by Kolmer (1926) and confirmed by Kolmer and his coworkers, indicate that the probable mode of action of bismuth compounds is directly spirocheticidal. He found by an *in vitro* method that soluble bismuth salts are actively spirocheticidal in dilutions of 1–50 000 to 1–225 000 (as dilution of bismuth metal) These concentrations are nearly those found in body fluids after therapeutic doses Tissue extracts contrary to Levaditi do not enhance but actually reduce the spirocheticidal action. This action is not affected by the absence of molecular oxygen and is probably due to the bismuth compounds as such. It may however rest on an affinity for sulfhydryl groups in the spirochete (*cf* Levaditi, glutathione) Kolmer Kast and Rule agree there is no reasonable doubt that bismuth is directly spirocheticidal both *in vitro* and *in vivo* but consider it an open question whether or not the element slowly dissociates from deposits of the compounds as administered intramuscularly for these effects, or whether the compound first effects a union with the tissues from which organic bismuth complexes the metal is slowly dissociated with direct spirocheticidal activity

Collateral Effects of Bismuth.—Certain other effects of bismuth on the animal organism deserve note The metal is a very effective diuretic, the early induction of diuresis being similar but even more marked than in the case of mercury and limited to a less degree by subsequent toxic injury to that organ

which is of course less with bismuth A number of observations on the effect of bismuth upon the blood picture have been recorded and are somewhat conflicting probably depending on dosage and salt employed In contrast to the marked anemia-producing qualities of mercury bismuth may produce a temporary slight reduction in erythrocytes followed by a definite rise. According to Marcozzi and Neuber the absolute and relative characteristics of the leukocyte count are also slightly affected (*cf* Fishback and Fishback, 1937 polymorphonuclear increase in rabbits.) Ramsas, Brown, Saleeby and Schamberg have shown that the effect on renal and nitrogen eliminative capacity and metabolism is dependent on injury to the kidney Administration of bismuth in amounts such as are used in the treatment of patients with syphilis causes abnormal changes at the site of provisional ossification of growing long bones. A succession of courses of bismuth treatment gives rise to a series of cross striations radiologically more dense than the normal bone between them. As the bone grows the dense bands become further removed from the epiphyseal line and they become less distinct and eventually vanish Although these changes are evident only during the process of bone growth and represent abnormalities of bone growth, prolonged bismuth administration does not interfere with the rate of linear growth (Ruskin, Stadler and Jeans 1942)

Pharmacology of Bismuth.—Considerable advancement of our knowledge of the pharmacology of bismuth compounds is due to the prodigious effort of several American groups of pharmacologists and chemotherapeutists including Sollmann and Cole Hanzlik, Kolmer and their coworkers

Absorption.—Many of the general principles governing the absorption of heavy metals have been worked out or elaborated in the intensive chemical study of bismuth All bismuth preparations injected into the musculature produce necrobiotic and necrotic processes as has been stated. The injury is least marked with water and tissue-soluble preparations, is more distinct with water-soluble and tissue-insoluble preparations and is very marked with aqueous and oily suspensions of insoluble bismuth salts Suspensions of colloidal metallic bismuth seem to produce somewhat less injury than the suspensions of the insoluble salt but the regenerative process seems to extend over a very long period Tissue- and water-soluble preparations are the most rapidly absorbed followed in order by the water-soluble and tissue-insoluble preparations, the aqueous and oily suspensions of insoluble salts and finally the suspensions of colloidal metallic bismuth which show the slowest absorption *from the site of the injection Insoluble bismuth soap formation has* been confirmed by Aubrey for man, in the case of the hydroxide.

Systemic bsorption of bismuth compound in nimals is demonstrated by determining the toxic effects nd fatalities with large doses, by the rat of disappearance of bismuth compounds from sites of injections and by their appearance in the urine after administration by various routes—intramuscula or oral.

The study of bismuth absorption by the use of the -ray originally applied to mercury while recognised as practically valuable method in man is show t contain serious factors of error due in part to the deposition of calcium at the injection sit Some of the differences in published results are probably due t difference in the rate of bsorption which has been shown by Cole by Gruhzit, and by Montagne t be due t the difference in the rat of absorption from f tty tissue and active and inactive m scular sites. Sollmann and Henderson (1936) have shown in dogs, for example that thiobismol is bsorbed practically completely in tw hours. With sod um tartrat and presumably other compounds studied, the amount absorbed increased materially beyond three hours Bet een eighteen nd fifty-one hours, there is little further absorp-

tion, if any so that the data are treated together for this span. Increased dosage increased the amount of the metal absorbed, but the percentage absorbed did not appear to be materially affected by doubling or tripling the dose The preparations may be arranged in four groups, in descending order of median absorption: the highest is thiobismol the other watery solution range in the second and third groups, the oily solutions in the second, third, and fourth groups, and the oily suspensions in the fourth, or lowest, group. With few exceptions, this order corresponds to the order of clinical excretion.

Considerable controversy has appeared in the literature recently as to whether bismuth administered orally is absorbed. Early observers (Sazerac and Levaditi, 1921 Fournier and Guénot, 1921) believed bismuth ineffective orally Serefis (1931) revived this mode of administration by developing for oral use a complex (half-ne mixture of bismuth chloride and sodium citrate in glycerine (bismutrat) which he claimed is absorbed and is actively antisyphilitic. It has given equivocal clinical result (Thomas 1937) and rather variable but slight bismuth excretion. Rein and Sulzberger (1936) found it promising as a prophylactic in experimental syphilis but Kemp and Rosahn (1936) found it, as well as potassium bismuth tartrate without demonstrable curative effect when given orally Kolmer (1937) stated that potassium bismuth tartrate orally cured 42 per cent of the rabbits with acute syphilis treated. In 1931 he also found that sobisminol orally is absorbed sufficiently in repeated doses to effect biologic cure in syphilitic rabbits Stratton (1938) found the urinary excretion of bismuth in rabbits after the use of several oral bismuth preparations to be satisfactory for bismutrat and sobisminol, less so for potassium bismuth tartrate and none at all for bismodide Hanzlik and his associates (1937 1938) made quantitative studies of absorption of bismuth from the ligated stomachs and ligated loops of intestine of rabbits and white rats after injection of sobisminol solution. In limited series, approximately 50 per cent of the sobisminol solution placed into empty ligated intestine or stomach was found to be absorbed in from one to eight hours. A limit of bismuth absorption was reached at the end of twenty to twenty-four hours. The cause of this limit was due to relatively large quantities of bismuth in the intestinal or stomach wall.

They also found that absorption of sobisminol solution or mass in man, as evidenced by clinical studies, appears to be rapid and sufficient to maintain antisyphilitic levels of bismuth concentration in the body X-Ray examination of gluteal regions in patients each receiving adequate antisyphilitic therapy in the form of injection of sobisminol failed to reveal shadows.

Hanzlik has directed attention to the difference in behavior of bismuth acting as anion and as cation. The familiar preparations contain bismuth as cation but he believes there is reason to expect that certain combinations, the bismuthites in which the metal appears as anion, have superior penetrative properties for certain tissues, including especially the nervous system. The claim of bismuth penetration of the nervous system after injection of anionic bismuth is not accepted by all. Klauder (1934) for example failed to find cerebral penetration after injection of sodium iodobismuthite (the bismuth compound in iodobismitol with saligenin N.N.R.) While others have confirmed the presence of bismuth in the cerebrospinal fluid (Strandberg and Sjögren, 1933, Schujman and Macchi Campos, 1935 and Tsing, 1933) While Hanzlik' (1936) impersonal and disinterested reexamination of the question resulted in confirmation of previous positive results, the question is still open. An interesting sidelight of the penetration of bismuth into the central nervous system with possible clinical applications is the finding of Newman and Richardson (1937) that alcoholic ingestion by their experimental animals definitely increased the penetration of bismuth, given as iodobismitol, into the central nervous system.

Circulation, Concentration, Tissue and Blood Distribution of Bismuth.—In general the amount of bismuth in the viscera is determined chiefly by the total dosage of the metal administered. The concentration of bismuth in the blood, ranges in the experimental animal from 1/10,000 to 5/10,000 mg. of metal per gram of blood. If the rate of injection is managed, the highest bismuth level appears at the end of the fourth hour is maintained for twenty-four hours and then slowly declines, the metal being present in minute amounts over a period ranging from weeks to months. Hanzlik (1935) found that the median concentration of bismuth in the blood of patients is of the order of 1:3,000,000 more or less H and his coworkers stat that with the average adult receiving iodobismuthate there is 0 1 mg. of it unchanged in 100 cc of blood Henderson (Cole 1936) places the concentration of bismuth in the blood at 0.05 to 0 1 mg. bismuth per 100 cc. of blood. Hanzlik believes that most of the bismuth in the blood is in the plasma. Bauer and Strauss (see von Oettingen review) believe the bismuth to be bound to the euglobulin fraction of the serum protein but Lomholt found it uniformly distributed through all fractions of the serum, the serum itself containing 78 per cent, and the cellular elements the remainder The striking difference of bismuth from other metals is indicated in its absence from the erythrocytes (compare lead)

The concentration of bismuth in the organs of the body after intramuscular injection is high

which is, of course less with bismuth A number of observations on the effect of bismuth upon the blood picture have been recorded and are somewhat conflicting, probably depending on dosage and salt employed In contrast to the marked anemia producing qualities of mercury bismuth may produce a temporary slight reduction in erythrocytes followed by a definite rise. According to Marcozzi and Neuber the absolute and relative characteristics of the leukocyte count are also slightly affected. (cf Fishback and Fishback, 1937 polymorphonuclear increase in rabbits) Ramsey Brown Saleeby and Schamberg have shown that the effect on renal and nitrogen eliminative capacity and metabolism is dependent on injury to the kidney Administration of bismuth in amounts such as are used in the treatment of patients with syphilis causes abnormal changes at the site of provisional ossification of growing long bones A succession of courses of bismuth treatment gives rise to a series of cross striations radiologically more dense than the normal bone between them As the bone grows the dense bands become further removed from the epiphyseal line and they become less distinct and eventually vanish Although these changes are evident only during the process of bone growth and represent abnormalities of bone growth prolonged bismuth administration does not interfere with the rate of linear growth (Ruskin, Stadler and Jeans, 1942)

Pharmacology of Bismuth.—Considerable advancement of our knowledge of the pharmacology of bismuth compounds is due to the prodigious effort of several American groups of pharmacologists and chemotherapeutists including Sollmann and Cole, Hanzlik, Kolmer and their coworkers

Absorption.—Many of the general principles governing the absorption of heavy metals have been worked out or elaborated in the intensive chemical study of bismuth. All bismuth preparations injected into the musculature produce necrobiotic and necrotic processes as has been stated The injury is least marked with water and tissue-soluble preparations, is more distinct with water-soluble and tissue-insoluble preparations, and is very marked with aqueous and oily suspensions of insoluble bismuth salts. Suspensions of *colloidal metallic bismuth seem to produce somewhat less injury than the* suspensions of the insoluble salt but the regenerative process seems to extend over a very long period. Tissue- and water-soluble preparations are the most rapidly absorbed followed in order by the water-soluble and tissue-insoluble preparations, the aqueous and oily suspensions of insoluble salts and finally the suspensions of colloidal metallic bismuth which show the slowest absorp*tion from the site of the injection. Insoluble bismuth soap formation has* been confirmed by Aubrey for man, in the case of the hydroxide.

Systemic absorption of bismuth compounds in animals is demonstrated by determining the toxic effects and fatalities with large doses, by the rat of disappearance of bismuth compounds from sites of injections and by their appearance in the urine after administration by various routes—intramuscular or oral.

The study of bismuth absorption by the use of the -ray originally applied to mercury hile recognized as practically valuable method in man is shown t contain serious factors of error due in part t the deposition of calcium t the injection site Some of the differences in published results are probably due to difference in the rate of bsorption hich has been show by Cole by Grabert, nd by Montague to be due to the difference in the rat of absorption from fatty tissue nd active and inactive muscular sites. Sollmann and Henderson (1936) have shown in dogs, for example that thiobismol is absorbed practically completely in t hours. With sod um tartrat and presumably other compounds studied, the amount absorbed increased materially beyond three hours. Between eighteen and fifty-one hours, there is little further absorp-

excreted in considerable amounts by the kidney after twenty to thirty days or longer. Massage of the injection sit can produce the ppearance of the metal in the blood within two hours in dogs, the ppearance being delayed t enty-four hours without massage. The most rapid elimination occurs with the water-soluble salts, such as sodium bismuth tartrat (Hanzlik) and sobisminol. (Hanzlik et al. 1936, Sollmann et al. 1938.)

It ppears that several factors are involved in the excretion of bismuth after intramuscular injection (Von Oettingen). The most important are the solubility and the difference bet een aqueous and oily suspensions. The ater-soluble preparations are promptly excreted and the excretion, after having reached the maximum, decreases rather rapidly. When suspended in oil the soluble preparations because of slower bsorption are excreted more slowly. Insoluble preparations suspended in water are excreted more rapidly than those suspended in oil and it seems that the type of excretion of the oil suspension depend also on the chemical composition of the bismuth compound (cf. Cole et al. 1938). The slowest excretion occurs with colloidal metallic bismuth preparations. The age of the patient and the condition of the circulatory and excretory apparatus is of importance for Hanzlik and associates have shown that the excretion of bismuth is perceptibly smaller in edematous patients than in normal persons. The excretion of bismuth is delayed by doses sufficiently large to injure the kidney. Hanzlik, M rtens nd coworkers found that increasing the dosage of bismuth products tends to reduce the total urinary excretion independent of the time factor and regardless of the bismuth product and the vehicle used. They strongly emphasize the objectionable and dangerous character of insoluble products of bismuth and insoluble vehicles from the standpoint of dangerous cumulative effects. They insist that in many cases the vehicle is quite as important as the drug. Corson, Decker and Williams (1940) were able to induce urinary excretion of bismuth from patients with bismuth depots by oral administration of ammonium chloride.

In the case of bismuth administered orally there is definite urinary excretion but the major portion of the metal excreted is by the fecal route. Considerable amounts of the bismuth of sobisminol are presumably retained in the body (probably in the intestinal wall) supposedly t be excreted gradually over long periods in minute quantities. Bismuth ppears in the urine beginning the day after administration nd reaches peak on about the fourth day after single doses (sobisminol) and on the tenth and t enty-eighth days after from 3 to 12 doses respectively. Sollmann, Cole and Henderson (1938) showed that the oral administration of sobisminol in doses of 3 capsules (140 mg. bismuth) and of 9 capsules (420 mg. bismuth) daily for three weeks gave curves of urinary excretion resembling closely the course and degree of those given by the intramuscular use of the water-soluble and oil-soluble preparations. The dose with the oral preparation, however had to be higher than ith the intramuscular preparations. Hanzlik and his coorkers (1937), found the urinary excretion greater after intramuscular injection of sobisminol than after oral administration. (Confirmed by Brown and Kolmer (1942) for sobisminol and potassium bismuth tartrate.) Urinary excretion was demonstrable one half hour after oral administration. Such urinary excretion as found to vary directly with the dose, to manifest cumulative tendency and to outlast the period of administration. Urinary excretion wa retarded or reduced by the presence of food and varied considerably with the individual.

The Toxicology of Bismuth.—The toxicity of bismuth in syphilological practice is remarkably low. In fact, it is so low as to lead the incautious easily into such definite abuses of the drug, as its intravenous administration. The symptoms of severe bismuth intoxication, made familiar by clinical and experimental experience include loss of appetite, vomiting and diarrhea, followed by stomatitis with ulceration of the tongue, severe necroses of the gums tongue and buccal mucosa and black deposits of bismuth sulphide in the mucous membranes. Weakness, slowness and incoordination of movement develop terminating with tetanic convulsions, paralysis and death.

A striking feature of the postmortem picture in animals is the black discoloration of the cecum limited very sharply by the ileocecal valve and extending throughout the thickness of the bowel wall. Lucke and Klauder found that after the tartro-bismuthate pronounced changes occurred in the epithelium of the convoluted tubules of the kidney with degeneration and deposition of calcium salts, as in all heavy-metal poisoning. Kolmer, Brown and Rule (1939) found that this injury is the same for all bismuth compounds studied and believed the responsible substance was elemental bismuth, view supported by Longly, T tum and Clausen (1940–1941) ho believed that bismuth compounds ultimately act in common manner probably due t

common end product and the variations in toxicity and therapeutic activity of different preparations may be accounted for largely by the differences in the rat of absorption from th intramuscular depots. I general the toxicity of bismuth compounds is conditioned by the route of administration, chemical constitution, solubility (the more soluble, the more toxic) and vehicle The bismuth content evidently does not have so definite relationship t toxicity as is generally believed (Kolmer Brown and Rule, 1930). The glomeruli are relatively unaffected The lesions in the liver are less conspicuous, but fatty infiltration and focal necroses may occur Beerman has collected the available literature on fatal bismuth intoxications in man. They are fortunately very rare. Hahn (1941) found only one f tality attributable t bismuth among the 19,580 patients treated with bismuth in Johns Hopkins Hospital between January 1924 and June 1940 (one fatality t pproximately 175,000 injections of bismuth subsalicylate) Acutely fatal intoxications have most frequently followed intravenous injection and take the form of species of colloidoclastic shock. Sudden collapse syncope with respiratory difficulty cyanosis, disappearance of the pulse and convulsive movements usually terminate within few minutes in death. In the more protracted intoxications in man the structures evidently principally involved are the gastrointestinal tract, the liver and the kidney The remarkable margi which exists between the curative dose and the maximum tolerated dose in animals (the rabbit, used in these experiments, however is very tolerant of bismuth) is well indicated by the statement (Kolmer Brown and Rule, 1930) that bismuth subsalicylate is tolerated up to 800–1000 mg per kilo (hite rats) while 6 mg per kilo is the minimal curative dose in rabbits.

Clinical Reactions to Bismuth.—In order to save space a summary and classification of all known forms of bismuth intoxication are given in Fig. 75 which summarizes especially the very large French experience, probably the largest of any single national group as presented in the Reunion of French speaking Dermatologists at Strasbourg in 1930 Among the more interesting and perplexing reactions to the practitioner should be included especially "bismuth grippe, which is at its onset nearly always mistaken for an intercurrent infection but which repeats itself with each injection. Klauder has called attention to the importance of fetor as a sign of approaching chronic bismuth intoxication, a point which we have repeatedly verified It may precede the appearance even of the blue line but as a rule occurs later The blue line is frequently not in reality a line but an isolated segment of discoloration at the contact of the base of one or two teeth with the gum, appearing *most often at the site of a heavy filling or where caries and pyorrhea are in* progress. It is not a contraindication to the continuance of treatment in the majority of cases and, while rather persistent, is to some extent controllable by an adequate mouth prophylaxis as later described. Bismuth pigmentation of the mucosae and gums clears slowly when the drug is stopped Severe bismuth stomatitis appears to differ from severe mercurial stomatitis in a lesser tendency to edema and salivation and a more marked tendency to abrupt necrosis which has been so severe as to suggest an agranulocytic factor in one reported case with hemorrhages into the skin.

The mechanism of bismuth stomatitis nd bism th pigmentation of the mucosae as studied by Ascolay is locally t least not unlike that of mercury as studied by Almqvist, Beeson and others in that relat vely insoluble bismuth sulphide is deposited in the capillary walls at sites where hydrogen sulphide is being produced by putrefactive decomposition of proteins under saprophytic bacterial action in the mouth. Presumably this explains too the deep pigmentation in the alls of the cecum especially The bismuth sulphide acts as local irritant, causing necrosis with hemorrhage and breakdown of the involved tissues in severe cases. The rational remedy as in the case of mercurial stomatitis, is direct attack on the foci of saprophytic infection in the mouth by vigorous dental preparation and prophylaxis Even though it leads all other forms of reaction as cause for discontinuance of treatment (see Fig 76) stomatitis is relatively much less import nt in bismuth tha in mercurial therapy even prophylactic precautions being capable of considerable relaxation (See Chapter IX.)

Fig. 75

TOXICOLOGY OF BISMUTH

I. **Local Reactions at Injection Site**

Pain and induration: Dependent largely on salt, state of division of drug, vehicle and technic. There is also a rare local anaphylactoid reaction with pain, enormous swelling and fever (Gougerot, Stokes)

Arterial embolism: Occurs once in every 8,000 to 15,000 intramuscular injections (Sulzberger and Baer). Four types as follows (Petges and Joulia, Barthélemy *et al.*, Gammel) due to emboli of bismuth or oil in the superficial capillaries

(*a*) Local exanthem—a roseolar eruption around the injection site

(*b*) Phlyctenular and ecchymotic plaques (venous embolism)

(*c*) Livedo (bluish network) and superficial necroses of the skin (at site of exanthem)

(*d*) Deep gangrene due to arterial embolism (fat, or in whole at injection site, or thrown to a distance, glans penis (Kimberly)), bladder wall (Cole). Preceded by sudden, violent pain, pallor of the affected part. May be followed by foot drop.

Abscess: Early or delayed (Vigne Fernet) may be fatal (Foged)

II. **Systemic Reactions.**

Nitritoid or vasomotor crisis (following both intravenous and intramuscular use).

"Colloidoclastic shock" Collapse and death immediate or preceded by jaundice, stomatitis, and delirium usually following intravenous use

Embolic symptoms (regional). Pulmonary cerebral, due to the injection mass, not the drug.

"The bismuth asthenias" (*a*) Simple with cephalgia, rheumatoid pains, backache weight loss; (*b*) "bismuth grippe, with aches and pains and fever suggesting acute infection followed by weight loss; ( ) grippe with psychic symptoms (impotence (Cayrel), crises of respiratory anxiety)

Stomatitis Fetor often first symptom (Klauder). Blue line due to deposition of bismuth sulphide (insoluble) by interaction with H_2S from mouth organisms. Gingivitis due to bismuth sulphide irritation. Ulceration, mucous casts. Blue or blue-black spots (sulphide deposits) (Ascoley McCarthy and Dexter). Necrosis of the jaw and tongue. **Vincent's angina** (*Arwyl-Davies*) (*agranulocytosis?*).

Cervicovaginal melanosis of *stomatitis* (Wiener; (vaginal) Clement Simon), may be spotted, erosive, ulcerated, scarred. Mild processes asymptomatic and unnoticed, severe type rare.

Gastro-intestinal tract (Rare) (*a*) Abdominal cramps, diarrhea (*b*) ulcerative enteritis and colitis (Millan) Melanosis of colon.

Nervous system Vagosympathetic disturbances (vertigo, suffocation, sweating, palpitation, respiratory crises) Polyneuritis (Critchley) Herpes zoster (Becker) Insomnia, nervousness.

Skin: (*a*) Urticaria; (*b*) general edema (Vigne) (*c*) purpura; (*d*) erythemas, morbilliform and scarlatiniform Nicolas *et al.*; ( ) erythrodermias and exfoliative dermatitis due to arsenicals and bismuth (Jordan and Osborne) (*f*) seborrheic eruptions; (*g*) lichenoid eruptions; (*h*) papular exanthem (Lutz-Pautrier resembling syphilid.) Pityriasis-rosea-like eruption (Skolnick and Aleshire) ( ) Pemphigoid eruption, Irgang, Sala and Alexander; Shaffer and Collins (*j*) Miliaria-like eruption. (*k*) Bismuthia (blue-black bands, covered parts grey reactivation of latent argyria (?), Gougerot and Blum Loeth, Sutton, McMullen and Muehlberger) Bismuth may reduce argyria from silver arsphenamine (Spiegel)

Liver Jaundice Nomland *et al* Kulchar and Reynolds, Gott and Doyle Lane (focal necroses) Acute necrosis of liver (Wolman) Rare

Kidney (Rare) (*a*) Polyuria (Blum) (*b*) albuminuria (and stomatitis, Peters; in tropics, Wells and Sewell); (*c*) hemorrhagic nephritis (Gallot, Aubertin and Destouches, Shaffer and Collins) (*d*) oliguria and anuria (Gatt and Moutier Eltsen).

Blood Evidence of slight erythropoietic disturbance still uncertainly defined. Rare agranulocytosis.

Arthralgia (Gemmer)

Therapeutic shock effects Not properly classifiable as bismuth reactions.

The cutaneous manifestations are now well recognized in man urticaria and general edema with the development of brawny plaques and the various forms of toxic erythema being the most frequent, but all forms of cutaneous reaction being in reality quite rare The remarkably low toxicity of therapeutic doses for the kidney is evidenced by the relatively few reports of significant renal damage Hudelo and Rabut having observed albuminuria only four times in 10 000 injections.

The order of importance of clinically observed reactions can be gauged by the frequency with which they force the stoppage of treatment as presented in Fig. 76 from Vigne s summary of 76 478 injections at the Strasbourg Reunion. Carrera in 42,000 injections saw weight loss 6 times, herpes zoster 5 nitritoid reaction 4 stomatitis (severe) 3 skin eruptions 3 absolute intolerance 2 cases.

Vehicles and Routes of Administration of Bismuth.—Bismuth remains, in spite of pharmaceutical propaganda, a one-route drug and its administration by intramuscular injection is the only method countenanced by scientifically grounded present-day practice. Oelze, Lomholt, Klauder and Kolmer (1935) have demonstrated the relative uselessness of bismuth inunctions the drug

Fig 76

PERCENTAGE DISTRIBUTION OF BISMUTH REACTIONS IN SYPHILIS TREATMENT MARKED ENOUGH TO REQUIRE DISCONTINUANCE OF THE DRUG (VIGNE)

	Per cent.
Stomatitis	72
Asthenia and grippe	10
Local pain (severe)	9
General reactions	6
Cutaneous eruptions	5
Abscess	3 3

Vigne estimates that of all reactions, 8 to 10 per cent will require stoppage of the drug.

by mouth is comparatively effective, however when administered in the form of sobisminol mass (sodium bismuthate soluble Hanzlik) Attempts have been made to give bismuth salts intraspinally (Gallardo, Lafora, Agramunt) but the method is dangerous and has no evident advantages. The high toxicity of intravenous administration can be realized by Kolle s example toxic dose 34 mg. of a 50 per cent aqueous preparation minimum curative dose, 20 mg and again toxic dose, 100 mg tolerated dose 90 mg minimum curative dose, closely approximating 100 mg These narrow margins of safety should be compared with a margin of three to ten times the effective therapeutic dose as compared with the toxic dose on intramuscular administration (Raziss and Severac)

The fatal dose in rabbits and dogs by intramuscular injection is five to ten times higher even when the soluble bismuth compounds are given in dilute solutions by slow intravenous injection "drip method" (Sollmann and Seifter 1942)

Bismuth Preparations in Common Use in the United States.—The number of bismuth preparations available to the physician is legion In order to guide the physician to the better established and widely used preparations, we are

submitting in Fig 77 the preparations described in New and Nonofficial Remedies (1942) of the American Medical Association. By judicious employment of these compounds one may accomplish any desired bismuth therapeutic effect. According to Cole Sollmann and Henderson (1930) one may use the following scheme for bismuth therapy and obtain a more or less continuous urinary excretion of 2 to 4 mgm. of the metal daily which would indicate a satisfactory continuous therapeutic level in the blood stream

For rapid bismuth effect

Sodium bismuth tartrate in water	Injections intramuscularly three times a week
Sobisminol, Iodobismitol	Injections twice weekly

If the patient can be persuaded to return twice a week for injections probably the most efficient preparations in terms of high bismuth excretion are sobisminol and iodobismitol

For a somewhat slower but efficient bismuth effect

Biliposol, Bismocymol	Injections every five days to once a week

For an effect slow in building up but eventually sustained

Injections of oil suspensions of

Sodium potassium bismuth tartrate, Bismuth subsalicylate	Once weekly

For patients with acute syphilis or those sensitive to arsenical, when a rapid but prolonged effect of bismuth is called for Sollmann Cole and Henderson (1938) suggest a graded sequence of soluble bismuth preparations with continued weekly injections of an oil suspended bismuth preparation.

General Dosage Rule for Bismuth Preparations.—While the dosage of the listed preparations is given in the table, it is worth while to attempt a formulation of a general dosage rule for bismuth preparations. This has been undertaken by Lomholt on the basis of the oxychloride, which he has extensively investigated. Lomholt's rule, as it might be named calls for a dosage of 0.5 mg of bismuth metal per kilo of body weight per day In utilizing such a rule it is apparent that the user must know the metallic content of the bismuth preparation he employs and this should be placed by the manufacturer on the label of each bottle or ampule. It must further be recalled that the oxychloride which Lomholt employed carries 80 per cent metallic bismuth and is regarded as one of the best absorbed and best eliminated of available bismuth preparations of the water-suspended group When an oil-suspended preparation is administered the slower absorption and the greater tendency to accumulation must be allowed for The estimate of 0.5 mg per kilo per day is, however conservative for rapidly absorbed and eliminated preparations and where short courses or long rest intervals are allowed may be increased to 0 7 mg with the realization, however that there will be definite accumulation of the drug with insoluble or oil-suspended salts during the period of treatment. The desirable therapeutic level of bismuth in the blood stream as indicated by a satisfactory daily urinary bismuth excretion (2 to 4 mgm.) may also be attained by using the bismuth preparations as classified by Cole, Sollmann and Henderson (1939) (abov) Thus, for a man weighing 65 kilos

Fig 77

BISMUTH PREPARATIONS FOR TREATMENT OF SYPHILIS LISTED IN NEW AND NONOFFICIAL REMEDIES, 1942

Trade name	Chemical constitution	Preparation.	Approx. per cent Bi.	Single therapeutic dosage in man.		Frequency of injection.	Manufacturer or distributor
				Compound.	Metallic Bi.		
		For Intramuscular Use *Water Soluble*					
Bismosol	Potassium sodium bismuthotartrate.	Solution glucose.	35	1 cc. (0 1 Gm.)	0 035 Gm.	3 weekly	Merck.
Bismuth sodium tartrat	Basic sodium bismuth tartrate.	Solution sucrose.	72 7–73 9	2 cc. (0 03 Gm.)	0 022 Gm.	3 weekly	Searle.
Potassium bismuth tartrat	Basic potassium bismutho-tartrat	Solution sucrose.	64	2 cc. (0 06 Gm.)	0 032 Gm.	3 weekly	Abbott.
Thiobismol	Sodium bismuth thioglycollat	Dispensed as powder soluble in water	38	0 2 Gm.	0 076 Gm.	3 weekly	Parke, Davis.
Iodobismitol with benzocaine	Sodium iodobismuthit (Sodium bismuth iodide) and benzocaine	Solution propylene glycol.	21	2 cc. (0 115–0 133 Gm.)	0 024–0 027 Gm	2 weekly	Cutter Squibb.
Sobisminol solution.	Undetermined as yet.	Propylene glycol and water	10 25–20 25	2 cc. (0 2 Gm.)	0 030–0 041 Gm.	2 weekly	Cutter Lilly Squibb.
		Oil Soluble					
Bismocymol	Basic bismuth camphocarboxylate.	Solution olive oil.	37–40	1 cc. (0 13 Gm.)	0 05 Gm.	2 weekly	Abbott.

Oil Suspended							
Potassium bismuth tartrat	Basic potassium bismuth tartrat	Suspended in olive and almond oils	64	2 cc. (0.2 Gm.)	0.128 Gm.	weekly	Abbott.
Bismuth subsalicylat	Bismuth subsalicylate.	Suspended in peanut oil.	58	2 cc. (0.2 Gm.)	0.114 Gm.	weekly	Abbott and numerous others.†
Oleo-bi	Bismuth oleat	Suspended in olive oil.	19.8	2 cc. (0.05 Gm.)	0.100 Gm.	eekly	Hoffman-La Roche.
Tartro-quinobine	Quinine bismuth iodide 0.072 Gm. (18–20.1 per cent Bi) and sodium potassium bismuthyl tartrat 0.032 Gm. (40.75–41.25 per cent Bi).	Suspended in olive oil.	27	1–2 cc. (0.1–0.2 Gm.)	0.027–0.054 Gm. approx.)	2 weekly	Alba.
Combination of Bismuth and Arsenic							
Bismarsen	Bismuth arsphenamine sulfonat	Dispensed as powder soluble in water	24 (13 per cent arsenic).	0.2 Gm.	0.05 Gm.	2 eekly	Abbott.
FOR ORAL USE							
Sobisminol mass	Undetermined as yet.	In capsules (0.75 Gm. each)	19.25–20.25	6–9 capsules 4.5–6.75 Gm.	0.900–1.35 Gm.	daily	Cutter Lilly Squibb

Also supplied in 3 per cent solution, each 2 cc. containing 0.06 Gm. of the compound.

† The data given are for typical preparation. Various modifications in vehicle, concentration of compound and local anesthetic are used by different manufacturers.

Bismuth Ethylcamphorate (Upjohn) (bismuth III salt of *d*-camphoric acid mono-ethyl ester) Epsoluble, used 2 cc. (90 mg. bismuth) weekly was accepted for N.N.R. on March 21 1942.

Fig 78.

SOME SUGGESTIONS FOR SELECTION OF APPROPRIATE BISMUTH COMPOUNDS

1 Know th metallic content of any preparation you consider
2. Be content with two or three preparations.
3 Make changes only on authoritative pronouncement i the literature ad by NNR acceptance not detail-man importunity ad leaflet campaigns.
4 Do not expect bismuth to do the work of an arsphenamine especially in early syphilis.
5 As rapid preparatory treatment less likely t produce shock effect than arsphenamine use ater-soluble bismuth salt in aqueous solution.
6 For th routine of bismuth therapy including ordinary preparation for an arsphenamine, use either an oil-suspended w ter-insoluble such as the salicylat or hydroxide which gives good absorption and good elimination with moderate or slight accumulation; or a liposoluble bismuth (camphocarbonat series, et)
7 When patients ar likely to be erratic and irregular; or the rest intervals long or prolonged effect is desired (one course a year) use the older oil suspensions (NaK Bi tartrate) if patient will tolerat some local reaction.
8 When bismuth is used with an arsphenamine at short intervals use preparation with rapid absorption and elimination—e. w ter-soluble Na Bi tartrat thioglycolate, liposoluble Bi t void cumulative effects.
9 When complex tonic and adjuvant effects ar desired, as i debilitated patients, late cases, elderly tabetics, cardiovascular wrecks, et se compound ith quinine, iodide arsphenamine such as the iodobismuthat ith or ithout another salt; or bismuth arsphenamine sulphonate
10 Regulat th dosage and interval by the bismuth ontent and the effect desired, not by single rule of thumb.
11 If injections are to be infrequent (eekly) use the high-metal content, oil suspensions, and give shorter courses (8 t 12 injections, average 10)
12. If intervals are to be short (t t five day) use B as under (8)
13. T reduce local reaction use lipoid suspensions (salicylat double suspensions such as tartroquinobine) liposolubles.
14 W t h the future in the literature of ( ) liposolubles (b) preparations ith special penetrations such as Bi as amon (iodobismuthit) and ( ) oral preparations (sobisminol mass)

the dose of 227 mg per week w uld require that an oil-suspended preparation uch a bi muth subsalicylate containing 65 mg of metallic bismuth per cc

Fig. 79

THE IDEAL BISMUTH COMPOUND FOR INJECTION

1 Constant metallic content and stability of salt.
2. Exact dosage (difficult in suspensions)
3. Post-injection depot absorption in three to seven da s, and i nown longer interval if accumulation is desired.
4 Constant excretion level permitting blood stream circulation
5 No local pain.
6. No abscesses.
7 Tissue-soluble (no granular depots, insoluble soaps, alcification)
8. Self-sterilizing.
9 Freedom from complications such as extens mouth deposits or ttack on special structures such vascular system and bone marrow
10. Good clinical result

(In part fter Cole et al., Ven. Dis. Inf 12, 143 April 20, 1931)

with 130 mg metal per optimum single dose be given e ery four to five days. If gi en on a weekly ba is the dose would ha e to be nearly 4 cc. of the sus-

pension. On the other hand a preparation such as quinine iodobismuthate with only 30 mg. bismuth per cc would have to be given in 2 cc. doses three times or more per week or in large single doses of 6 cc. weekly with much discomfort, to approximate the 227 mg optimum of Lomholt's rule. The less frequent injections usually used in clinical practice with the oil-suspended preparations allow for their slower and more erratic absorption.

An interesting commentary on the influence of total dosage of bismuth is presented in Hugo Müller's discussion of relapse under bismuth therapy (Jadassohn Handbuch) in which he discusses the dosage practice of Germany and France during the earlier years of the bismuth era. The emphasis of the French on bismuth led to a larger dosage per course and a larger total dosage, the amount administered being 1.6 to 3 Gm. bismuth metal in each series of injections. Earlier German practice, on the other hand, contained numerous reports of relapses, apparently based on a dosage approximating 0.75 Gm. Bi metal per course. German practice, according to Müller, early adopted the principle of simultaneous use of the arsphenamines, thus doing away with the tendency to relapse and escaping the disadvantages apparent in French practice for a time of albuminuria and other bismuth complications. Müller furthermore insists that the condition of the German population with respect to nutrition and resistance following the First World War was such that the large doses of bismuth could not be tolerated. In recent years the average dose per course in Germany has risen to 1.5 Gm. bismuth metal in combined therapy and 2 Gm. when used alone. It has also been contended that the quinine-iodine-bismuth combinations are as effective in smaller doses as the metal alone or in simpler combinations in larger doses. It will be apparent that giving the Lomholt optimum, 2 to 2.3 Gm. bismuth metal per ten-injection course is the more or less accepted practice of the present day

Rest Intervals with Bismuth.—The rest interval between bismuth courses must allow both for the absorption of the deposit depots and the return of the tissues to a condition favorable to further therapy When the larger doses of bismuth are being used a shorter interval than six weeks scarcely allows time for these changes to take place between courses and eight weeks is frequently desirable. If on palpation nodular deposits can be recognized before the beginning of the second course, the same caution should be observed which was familiar under the insoluble salt regimen in mercurial days. A nodular or indurated injection site means retained metal and may at any time, under unexpected trauma or other influences, give rise to toxic absorption It is, therefore, undesirable to use preparations giving rise to sharp local reaction and nodule formation in certain individual cases or to carry any bismuth course to the point of deep protracted and resistant infiltration of the injected tissues. In the case of oral bismuth medication (sobisminol mass) sustained therapeutic effects from the drug are obtained only during the period of administration. If treatment is stopped the antisyphilitic effect appears to stop (Scholtz, McEachern and Wood, 1939)

Clinical Effects of Bismuth in Syphilis.—While the action of a soluble bismuth salt is quite rapid, it does not equal that of the arsphenamines and may even be approached by that of a water-soluble mercurial salt administered daily Lévy's results indicate that there is little difference between the water-soluble and the liposoluble bismuth preparations in their spirillicidal action. Both of them, however are distinctly more effective than the insoluble preparations. Oral bismuth medication with sobisminol mass seems to produce clinical antisyphilitic effects comparable to those produced by bismuth administered intramuscularly but the time of observation is as yet too short for final evaluation. (Meininger and Barnett, 1939 Scholtz, McEachern and Wood, 1939)

Under vigorous treatment with a soluble bismuth salt, small primary lesions have been known to heal in from one to four or five days but the average course more nearly approximates

two or even three weeks, when involution of the induration is taken into account. The rate of disappearance of secondary syphilids varies with the type of lesion but has been well summarized by Fournier and Guénot, who found that mucous patches were healed in four to five days, the organisms disappearing by the first or second injection. Hypertrophic papules heal in several days and are resorbed in ten to twenty-five days. Simple roseola disappears in five to ten days, often with Herxheimer reaction lasting twenty-four hours. Papular eruptions require an average of 5 injections and an upper limit of 10, the time required ranging from fourteen to thirty-five days. Papulopustular eruptions require 10 to 12 injections with approximately the same time. Late syphilids of the skin and mucous membranes have impressed us as disappearing distinctly more slowly under bismuth than the early syphilids and definitely more slowly than under the arsphenamines. On the other hand, Fournier and Guénot reported the disappearance of serpiginous syphilids under potassium bismuth tartrate in ten to nineteen days and Duerty and Müller reported the astonishingly rapid disappearance of the notoriously resistant keratoses of the palms and soles after 2 or 3 bismuth injections. Gummatous lesions of the lip and nasopharynx respond rapidly 8 to 10 injections being an average requirement, but Müller reported a remarkable case with erythema-multiforme-like lesions and extensive destructive lesions of the pharynx which disappeared following 1 injection of Trepol. Relief of pain is said to be as striking as after arsphenamine when the drug is employed alone. Leukoplakia has been reported as responding, but our own experience accords with that of Simon and Müller to the contrary. The superiority of bismuth to mercury can be readily recognized in the now comparatively rare malignant syphilis. Azoulay reports a case of generalized papulopustular and ulcerative syphilid with fever that failed to respond to 30 mercurial injections but was healed in ten days with quinine iodobismuthate. Sobisminol mass orally caused disappearance of spirochetes in a median of four to five days from seropositive primaries and involution of the lesions in a median of fourteen days. Secondary lesions disappeared in about two weeks. Gummas were healed in from about three to five weeks. (Meininger and Barnett, Scholtz, McEachern and Wood, 1930.)

The response of visible syphilids to bismuth is as in the case of arsphenamine and the disappearance of spirochetes, one of the few clearcut ways by which the practitioner devoting himself to this work can measure the effectiveness of his bismuth preparations and his dosage and plan of treatment. It is for this reason that the foregoing details have especially been given. This statement, however, should not be interpreted as encouraging the use of bismuth alone in the treatment of early syphilis as a routine, for the concomitant use of the arsphenamines, as will be seen later, is absolutely essential.

Bismuth in Osseous Syphilis.—The action of bismuth in syphilis of the skeletal system is prompt and satisfactory, certain types of headache and joint pains in early syphilis disappearing in one to two injections. The action in osteitis, osteomyelitis and bone gumma is markedly superior to that of mercurials and iodides. Late syphilids of the septum and palate, often so notoriously resistant to both arsphenamine and mercury, may respond surprisingly to bismuth, as in the case reported by Müller in which healing of an extensive process followed two bismuth injections.

Bismuth in Hepatic Syphilis.—In syphilis of the liver bismuth is well tolerated in the early cases and the drug is particularly serviceable in those cases of complicating catarrhal jaundice following on previous arsphenamine administration in which it fills a wide gap between the poorly tolerated arsphenamine and the relatively ineffective mercury. In late syphilis, however, great caution in dosage must be observed if too rapid an effect is not to be secured, and we personally believe that there mercury and iodide is still the preferable treatment.

Bismuth in Renal Disease.—In renal disease, whether due to syphilis or not, bismuth has a distinctive place in treatment. Müller has observed good effects from bismuth in treatment nephrosis which made the use of either arsphenamine or mercury, previously employed, impossible.

Bismuth in Cardiovascular Disease.—The question of the effectiveness of any single drug in the treatment of syphilitic cardiovascular disease cannot be decided merely by symptomatic response as will be brought out in a subsequent chapter. It may, however, be said in general that bismuth is able to produce marked symptomatic improvement when very cautiously administered in aortitis and aneurysm. Lacapère and Laurent and Perrin have reported the recession of aneurysm under treatment. Wodtke also observed favorable results in connection with arsphenamine therapy. Blackford and Boland have reported good results from bismuth alone in congestive heart failure in syphilitic patients. The influence of bismuth as a diuretic in patients suffering from breach of compensation is considerable and points to the use of a salt such as the water-soluble sodium bismuth tartrate if such effects are desired. Hypertension associated with syphilis tolerates bismuth better than mercury but with uncertain outlook for improvement.

On the other hand, in severe cardiac involvement, especially with decompensation, we believe bismuth has serious dangers and the utmost caution must be used in its administration if it is employed at all. One of us (J. H. S.) has observed three deaths occurring within twenty-four hours after single injections of potassium bismuth tartrate in which there was no reason to expect a fatal outcome from the general aspects of the cases. Müller observed the sudden onset of dyspnea and pain over the heart in a previously compensated case following 0.25 Gm. bismuth, and states that 5 mg. of metallic bismuth should never be exceeded as an initial dose in cases exhibiting cardiac complications. Unfavorable effects on the coronary system are especially to be feared.

Bismuth in Neurosyphilis.—The action of bismuth in neurosyphilis has been extensively studied. While there can be no doubt of the response of individual lesions, including gumma, meningitis, myelitis and isolated nerve lesions, the general effect of the drug is inferior to that of a properly directed arsphenamine therapy so far as spectacular action is concerned. On the other hand, its slightly slower action is a positive advantage in the majority of cases in that it avoids sometimes serious therapeutic shock effect. While neurorecurrences have been known to occur where bismuth therapy was employed to the exclusion of arsphenamine in early syphilis, the slower and more prolonged action of the drug has been apparent in their postponement until some time after the cessation of treatment. The very interesting observations of the Breslau clinic on the incidence of neurorecurrence during the period that the German insurance clinics were forbidden the use of arsphenamine for reasons of economy indicates distinctly that the drug should not be used alone with the expectation that it will prevent relapse in the nervous system in early syphilis. Neurorecurrence after bismuth therapy has even been observed to clear up with the subsequent administration of mercury (Galliot).

In tabes the symptomatic effect of bismuth is notable and often gratifying. Bismuth alone, especially in the iodoquinine combinations and the more soluble salts, often gives surprising responses in lightning pains and may very favorably affect gastric crises. In optic nerve involvement bismuth theoretically escapes the disadvantages of the arsphenamines and yet should be superior to mercury. Improvement in bladder function, which is in some ways a species of test of the effectiveness of a system of treatment in tabes, has been observed under bismuth therapy alone (Scherber). Improvements in gait, in

libido and potentia, disappearance of Romberg sign, optic atrophy brought to a standstill or definite improvement in vision, are all recognized good effects Response to bismuth usually occurs early in the course, if it appears at all

In the therapy of paresis there is no justification for the use of bismuth alone and its combination with fever therapy and tryparsamide is not yet evaluated Vonkennel has shown that the content of bismuth in the cerebrospinal fluid is increased during exacerbations of fever in malaria. The favorable effect of bismuth on cerebrospinal fluid abnormalities is now demonstrated beyond question, the principal effect being upon cell count and globulin content rather than on the Wassermann reaction. Artom (see Handbuch) has stated that the order of recession of the findings is lymphocytes, colloidal reaction globulin reaction and Wassermann, a statement more or less true of all forms of combined treatment.

Bismuth serves at the present time best as a means of securing rather quick symptomatic improvement in nonparetic neurosyphilis without the risks of the arsphenamines and with the avoidance of therapeutic shock effects

Bismuth in Eye and Ear Syphilis.—In the acutely inflammatory processes, such as iritis, iridocyclitis, neuritis and neuroretinitis bismuth's superiority to mercury has already been demonstrated. A number of communications attest its harmlessness in primary optic atrophy (see Müller Handbuch, p 357) Interstitial keratitis responds to intensive bismuth therapy but we believe more slowly with oil-suspended insolubles than to arsphenamine or to the combination of arsphenamine and a soluble mercurial salt. In one patient one of us (J H S.) was able to watch the difference in effect between potassium bismuth tartrate in full doses intramuscularly once a week and the much more rapid progress made under mercury succinimide, a soluble mercurial salt, given four or five times a week. Both drugs were administered simultaneously with arsphenamine. The tendency to relapse and progress under the insoluble bismuth salt was controlled satisfactorily by the soluble mercurial. When bismuth is employed for these purposes it would therefore seem advisable to give preference to a water-soluble, frequently injected salt such as sodium bismuth tartrate

Syphilis of the eighth nerve responds well to bismuth and inasmuch as the injections need be given less frequently than in the case of a soluble mercurial convenience may dictate its use. It avoids the risk of localized therapeutic shock effect in the eighth nerve involvement of early syphilis. Syphilitic labyrinthitis responds favorably according to Pasini

Bismuth in Pregnancy—*Bismuth can be expected to make a very important contribution to the treatment of the syphilitic pregnant woman,* in view of its high renal tolerance and its comparative freedom from shock effects. Supposed abortifacient effects from bismuth led Pouget to disapprove of its use but no general objection on this score has appeared. Juliusberg (Handbuch) calls attention to the necessity for considering this possibility in the use of the quinine iodobismuthate the effect, however being due to the quinine and not to the bismuth. It is not, however advisable in the treatment of early syphilis to employ it to the exclusion of arsphenamine. Castallo and Rakoff (1938) found that quinine iodobismuthate afforded little protection to the fetus and was markedly inferior to arsenical therapy In late syphilis, however it has the great advantage of being much less likely to disturb the woman's immunity mechanism and can be used with reasonable caution throughout the pregnancy Klaften has demonstrated the feasibility

of combined bismuth-arsphenamine therapy using as high as 3 to 4 Gm of bismuth metal. This is now routine practice in the treatment of syphilis complicating pregnancy

Bismuth in Prenatal (Congenital) Syphilis.—The use of bismuth to the exclusion of other drugs in the treatment of prenatal syphilis has strong advocates both in this country and abroad both on the ground of excellent symptomatic effect and the fact that in the majority of its manifestations prenatal syphilis is a form of late syphilis (see Chapter XXI) in which the immunity mechanism and tissue defence are important and should be disturbed as little as possible in securing symptomatic results Wright has been particularly active in this country in advocacy of exclusive bismuth treatment for prenatal syphilis. Personally we believe that it should be used with arsphenamine as subsequently outlined.

Dosage scales for the use of bismuth in the prenatally syphilitic child began, for example, with 2 mg. per kilo (Hoffmann) 5 mg per kilo (Drouet) 1 to 5 mg. (Vigne and Galliot), using such preparations as the salicylate. Of the iodobismuthates the initial dose may be 2 mg. per kilo. Müller restricts himself to 2 to 3 mg. per kilo. Wright used 5 mg. per kilo of potassium bismuth tartrat with excellent results. Stokes and Ingraham use 2 to 4 mg per kilo body weight of bismuth metal eekly Injury to the kidney need no more be feared in infants and children than in adults.

Effect of Bismuth on the Blood Serological Reactions.—Sazerac and Levaditi demonstrated the possibility of reversal of the blood serological test by bismuth alone in their early studies on the effect of the drug. None the less, the behavior of the serologic reaction under bismuth differs distinctly both in our experience and that of a number of other observers, from the response of these tests under arsphenamine and mercury In seronegative primary syphilis there is a distinctly greater tendency to fluctuation with the appearance of weak positives alternating with negatives so that the drug seems somewhat less effective in holding the initial seronegative state of the patient in seronegative primary syphilis. Similarly the proportion of serological reversals secured in the early weeks of the disease is less under arsphenamine-bismuth than under arsphenamine-mercury therapy On the other hand, as shown by the studies of the American Cooperative Clinical Group the early difference in favor of mercury is ultimately met by the superior results of arsphenamine-bismuth therapy The more rapid action of the mercurial combination was apparent in the first three months. Emory and Morin Ducrey Pasini, Bloch and Radaeli have all noted this delayed action of bismuth and Martin, Nathan and Martin noted a high proportion of fluctuating though ultimately negative tests. A second effect of bismuth therapy on the serological tests is a distinct tendency to provocative action leading to the development of positive serological tests in patients previously negative during a rest period The recrudescence of the positive is followed by a slow but ultimate subsidence to negative under treatment, the patient often tending to remain positive (and correspondingly disappointed) for weeks or months after the completion of the activating bismuth course Provocative effects from bismuth have been repeatedly observed (Biberstein Müller and Kohlenberger) The influence of bismuth, intramuscularly administered, in the reversal of fixed positive serological tests has been favorably reported. The effect is probably as much that of a change in the angle of attack as anything

else. Bismuth therapy given simultaneously with arsenical seems to have a delaying effect on serologic reversal (Beerman 1939)

McCafferty and MacGregor reported 61 7 per cent response in 25 cases that had failed to undergo reduction in the intensity of the serological test in spite of prolonged treatment with arsphenamine and mercury Only 20 per cent, however achieved complete negatives. Simon reports 5 complete reversals in 8 cases.

Bismuth resistant Syphilis.—The existence of absolute resistance to bismuth is now fully established but is a comparative rarity comparable to arsphenamine resistance and certainly much less frequent than resistance to mercury

The presence of active *Spirochaeta pallida* in the primary lesion after 13.5 Gm. bismogenol was observed by Elmassow-Sternberg and Levy Metzger observed similar case in which there was subsequently immediate response to mercury cyanide. The steady progression of secondary syphilitic manifestations under 7 bismuth injections totalling 1 12 Gm. Bi was observed by Lortat-Jacob, and Roberti. Müller observed the excellent effect of repeated change from arsphenamine to bismuth in patient who became resistant first t one and then to the other Lehner observed the absolute resistance of an infiltrated plaque to arsenic, bismuth and mercury Beerman (1936) reviews the literature

Therapeutic Shock (Jarisch-Herxheimer Reaction) under Bismuth.—Therapeutic exacerbation of visible syphilitic manifestations in the primary and secondary stages of the disease can easily be observed with the majority of bismuth preparations and their occurrence in the deeper structures in late syphilis must therefore be inferred. As a rule the reaction is slower in its appearance than after arsphenamine. Böhme, however observed the reaction as early as eight hours after the injection of oil suspensions, including potassium bismuth tartrate. The intensity of the reaction is not necessarily proportional to the bismuth content, being evidently dependent upon the rate of absorption and dissemination of the drug and is said to be frequent with the iodoquinine combinations. The height of the reaction is usually reached by the second or third day after the administration and the course may be materially prolonged.

In the verage experience, the incidence of therapeutic exacerbation is from 15 to 20 per cent (Stirling, Levaditi and others) Edema and swelling of the primary lesion have been observed by Simon, Müller and others. Slight fever may develop in secondary syphilis. Painful lymph node enlargement has been observed by Truffi and Müller Milian regards headache following bismuth injection in early cases as therapeutic shock effect.

There is, therefore, abundant reason for caution in the use of bismuth in conditions involving the cardiovascular and nervous systems and the liver in order to avoid significant therapeutic shock effects. Werther has observed a cerebral therapeutic shock effect with signs pointing to localized edema of a focus in the internal capsule with recovery under silver arsphenamine. The known vasculotoxic effects of bismuth may well be added to therapeutic shock effects in dealing with cardiovascular syphilis, especially with coronary involvement.

Bismuth as Prophylactic.—Kolle experiments on the spirochetostatic effects of bismuth and its inhibition of development of the primary lesion have led to attempts to use the drug as prophylactic. The problem of systemic prophylaxis of syphilis is discussed in subsequent chapter but it may be said that in general it is more likely that the effort t use bismuth in this

way will simply cloak the asymptomatic invasion of the body by the *Spirochaeta pallida* rather than actually prevent infection. Sonnenberg and others (Ramljean and Tran-Tan-Phat, 1937 Lepinay and Levaditi, 1936) attempted the immunization of prostitutes with bismuth by injection and by mouth, with suggestive results. This was not confirmed by Rabut (1936) and Gaté and Cuilleret (1936) Sobisminol mass orally has not as yet been tried in human prophylaxis (Hanzlik, Lehman and Winkle, 1940) On the other hand, syphilis has been observed to develop in patients under active bismuth treatment for other purposes (Pinard) and Kolle experiments with bismuth "plugs" are being subjected to more conservative interpretation.

Contraindications to the Use of Bismuth.—Idiosyncratic or allergic reaction to bismuth is known (see Fig 75) One of us (J H S.) has observed one striking example of local edema of the buttock following the first injection and repeated after the second injection, completely crippling the patient for the time being and making the continuance of the treatment impossible. Exfoliative dermatitis following bismuth injection has been reported by O'Leary and the value of Besredka desensitization is suggested by Stirling. The tendency to permit neurorecurrence in early syphilis contraindicates sole dependence on the drug in this phase of the disease A decompensated heart condition especially with liver stasis, is recognized as a definite contraindication and the utmost caution in dosage must be used. Bismuth must be used with caution in nonsyphilitic hepatic disease In renal disease the presence of albuminuria as such is not a necessary contraindication to the use of bismuth, and Müller states that he has seen the drug even better tolerated than neoarsphenamine in small doses. Smechula has warned against the risk of inducing coma in diabetics through incautious bismuth therapy The kidney even if impaired, seems however to gain in tolerance of treatment for syphilis as McFarland showed for a large arsphenamine-mercury material at the Mayo Clinic and as subsequent studies of complications by the Cooperative Group have tended to suggest. The final strong contraindication to intensive bismuth therapy is the presence of a hemorrhagic diathesis of any type, including paroxysmal hemoglobinuria. The tendency to agranulocytosis should also be borne in mind. In tuberculosis, bismuth is apparently better tolerated than mercury but must be used with caution.

Comparisons of Bismuth and Mercury—A comparison of heavy metals is inevitably more difficult than a comparison of an arsphenamine with a heavy metal, owing to the slowness of action of the latter and the fact that the results must be gauged by such intangibilities as the effect on resistance and defence on the incidence of complications which may require years for their appearance and on the ultimate outcome of the disease It is, therefore, small wonder that comparisons of bismuth and mercury are still largely speculative and impressionistic. The gradual crystallization of opinion in the past ten years has led to two numerical formulations, both French, which fairly summarize present-day opinion. Milian rates arsphenamine as 10 bismuth as 7 and mercury as 4 in a numerical scale More recently Gougerot has revised these figures for his own experience to read arsphenamine 10 bismuth, 8 mercury 6 The discussion of bismuth by Müller in the Jadassohn Handbuch accepts only calomel and the gray oil as even the approximate equivalents in effectiveness of easily available bismuth preparations, at the present time. Conservative stands, acknowledging the usefulness of bismuth, but deprecating the complete replacement of mercury have been taken by De Stefani, Anwyl Davies, Wright (1936) Cannon and Robertson (1936) and ourselves. Lomholt, one of the foremost European students of bismuth and

mercury from the biochemical standpoint, definitely rates bismuth as superior to mercury from every standpoint.

The following facts accumulated by the Cooperative Clinical Group tend definitely to support the superiority of bismuth. The first concerns the incidence of cutaneous and mucosal relapse under arsphenamine-mercury and arsphenamine-bismuth. Of 1117 cases receiving arsphenamine and mercury exclusively 107 or 9 6 per cent, showed mucocutaneous relapse Of 608 cases receiving arsphenamine and bismuth exclusively 22, or 3 6 per cent, showed mucocutaneous relapse The second group of studies with reference to the effect of arsphenamine-mercury and arsphenamine-bismuth on the serological gradient in treated early syphilis has been alluded to. It appears that one year or more (delayed reversal) is required to reverse to negative the blood Wassermann reaction in 8.3 per cent of cases continuously treated with arsphenamine-mercury as against 2.5 per cent with arsphenamine-bismuth A larger proportion of patients treated with mercury therefore, show delayed serological reversal. Under intermittent treatment, arsphenamine-mercury fails to reverse the Wassermann reaction in one year or over in 22.4 per cent while arsphenamine-bismuth fails in only 13.8 per cent. Even with irregular treatment, arsphenamine-mercury fails to secure reversal in one year or over in 50 9 per cent as against 40 8 per cent with arsphenamine-bismuth. The tendency to a more rapid reversal of the Wassermann under arsphenamine-mercury in the first three months and the tendency for this difference to equalize itself and result in an ultimate superiority for arsphenamine-bismuth has already been mentioned (p 211) An interesting controversial sidelight, however is afforded by the fact that in this same series of statistical studies when treatment results were classified by years in the decade 1919 to 1928 no conspicuous jogs," representing advances in clinical or serological results, coincide with the years during which mercury has been in part superseded and bismuth has assumed prominence in the therapeutic methods of the five cooperating clinics One is thus left with the conclusion probably the nearest approach to truth obtainable under the circumstances, that therapeutic results in early syphilis are a matter of balance among the agents employed. Bismuth may support a weaker arsenical, while an effective arsenical may support the inadequacies of mercury In most cases, combined treatment secures a good result before the virtues of any combination are taxed to the utmost.

What Bismuth Does Best.—The influence of bismuth is not as yet fully determined with reference to the following points (1) its effect on tissue resistance and defence (2) any tendency to activate quiescent infections, manifested only by positive serological reaction with resultant progression and complication (3) induction of therapeutic shock in vital structures (4) effect on the prevention of various forms of relapse (5) spirochetostatic power meaning thereby its ability indefinitely to hold ground gained or with appropriate repetition of treatment, to reduce the infection to lifelong latency (6) retention of the drug in the body—how much?—how long? The last item is in process of evaluation through the admirable advances made in the biochemical study of the drug in recent years

Bismuth fits in with the arsphenamines so to speak, early and late in the management of syphilis for its use encourages resistance building at a time when the shortcomings of the arsphenamines in this particular are most serious. Its low toxicity does away with the objections operative in the use of mercury and the arsphenamines and its spirillicidal effect maintains a con

stant check upon the remultiplication of organisms during periods when arsphenamine treatment must be suspended There is, at least thus far no clinical evidence that it gives rise to treatment allergy as do the arsphenamines. Thus it should at least theoretically be possible to keep the early case of syphilis, by the use of bismuth as distinguished from mercury in a noninfectious condition throughout the entire progress of the cure the drug, moreover can be administered for longer periods in moderate dosage without fear of intoxicating effect than can mercury

Bismuth as Preparatory Treatment.—Another accomplishment of bismuth is as a preliminary to the use of the arsphenamines, where there is some fear of therapeutic shock following the initial administration of the drug. So satisfactory is the slower and yet effective action of bismuth in properly graded dosage in this particular and so free from undesirable complications, that it may almost be offered as a general rule of procedure that wherever involvement of the nervous system for example in early syphilis is suspected and in

Fig. 60.

WHAT BISMUTH DOES BEST

1 Fits in with the arsphenamines early and late. May be given with arsphenamine and with proper choice of salt, vehicle and dosage continuously over long period (see chapter on the Treatment of Early Syphilis)
2. Is an adequate, nonreaction-inducing therapy for symptomatic latency apparently not materially disturbing the body resistance and defence mechanism.
3. Effective in late syphilis with minor manifestations, voiding the risks of the arsphenamines.
4. Invaluable in arsphenamine- and mercury-resistant cases, including serological fastness.
5. Invaluable in arsphenamine or mercurial intolerance, especially rsphenamine intolerance or idiosyncrasy in early syphilis.
6. Useful in conditions contraindicating arsenic, as exfoliative dermatitis, liver injuries.
7 Useful in nephroses and impaired renal function.
8. Effective in tolerated dosage in old age.
9 Effective as more rapid preparatory treatment for arsphenamine combining the low toxicity and freedom from shock effects of mercurial inunction with the prompter favorable action on symptoms, of rsphenamine
10. Notably useful symptomatically in late neurosyphilis.

all cases of late syphilis except cardiovascular and hepatic disease bismuth is now the proper opening treatment and arsphenamine should be temporarily postponed. Particularly is the drug serviceable in initiating the treatment of patients who for one reason or another impress one as clinically latent but in whom a complete investigation including study of the spinal fluid cannot be made at the outset. The rapidity of action of bismuth is such that a period of from two to six weeks constitutes an adequate preparation in the absence of definite lesions, which is materially shorter than that required for the slower acting intramuscular mercurials and mercury by inunction.

Bismuth is a valuable alternate in all cases of intolerance of or resistance to either arsenic r mercury Where arsenical by-effects in the skin have interfered with treatment, as in exfoliative dermatitis, bismuth becomes the next choice. On the other hand where the continued use of mercury threatens renal injury a rest period followed by the substitution of bismuth may do away with the difficulty Since the advent of bismuth it has become possible to treat with some semblance of efficiency the relatively rare cases of absolute

intolerance to all the arsphenamines. Bismuth preparations serve a particularly useful turn in the treatment of late neurosyphilis in which symptoms overshadow the serological findings. In the absence of the "red flag" syndrome or preparetic spinal fluid formula and in the presence of pain, paresthesias and degrees of symptomatic disability and emaciation in which for one reason or another an arsphenamine is contraindicated bismuth is superior to insoluble mercury or inunctions both on the score of absence of complications and positive therapeutic effects

In dealing with the latent case in which, after careful examination, only the necessity for maintaining the *status quo* becomes apparent, bismuth is again distinctly superior to mercury on the score of greater effectiveness and lower toxicity as well as a lessened likelihood of disturbing immunity balance through the use of the arsphenamines. None the less, in just such cases, regard for the waning but still significant worth of mercury calls for some division of the field between the two. In the treatment of late syphilis with trivial manifestations, as, for example, gummatous lesions in older individuals, mercury by mouth or inunction is particularly useful because of its relative freedom from reaction-producing qualities, its therapeutic efficiency and its relatively painless administration.

Bismuth Shortcomings.—The weaknesses of bismuth have been repeatedly referred to The tendency to trust too much to it on account of its spirillicidal and healing power is a very serious matter in modern practice and justifies sharp criticism of some of its proponents, particularly among manufacturers of pharmaceuticals Under no circumstances except those of an absolute intolerance should bismuth ever be used without an arsphenamine in the treatment of early syphilis, the practice of certain French authorities to the contrary notwithstanding (See Chapter XIV on treatment of early syphilis.) In the treatment of syphilis of the liver and the heart, allusion has already been made to very clear-cut intimations of significant and dangerous therapeutic shock effects.

MERCURY

Since the second edition of this work was published, mercury has definitely become syphilotherapeutic history Administered by mouth, it still gives faint favorable therapeutic push occasionally of use in old age and in the most ticklish and difficult of therapeutic shock situations. By inunction it is still useful in hospital practice, in isolated situations where patients must for months and even years, carry on a mild and safe treatment, free from risk of shock effect. We believe still that it is a safer approach to the more difficult, advanced and badly damaged cases of hepatic and cardiovascular involvement than the more popular bismuth. As a soluble mercurial salt it is still an effective spirillicide and an efficient agent in the treatment of certain forms of syphilis of the nervous system. As a colloidal preparation it can, with reasonable safety and good effect, be used intravenously For this degree of usefulness, extended consideration of the biochemical, toxicological and pharmacological action of mercurial preparations is not warranted despite the excellent work which has been done both in this country and abroad. This, with the history of the drug can be reviewed in previous editions of Modern Clinical Syphilology and in the articles by Lombolt, Rosenthal and Almkvist in the monumental Jadassohn Handbuch. Guided by the foregoing considerations, the discussion here will be purely clinical

Clinical Reactions to Mercury.—The clinically recognized toxic reactions to mercury include

1. Cutaneous manifestations, including fugitive erythema, scarlatiniform erythema (Billo, 1941), urticaria, diffuse and circumscribed edema and an acute vesicular dermatitis. Numerous other mercurial dermatoses have been described (Wright, 1930). Through secondary infection scattered inflammatory oozing crusted and infiltrated patches and plaques of wide distribution may develop. Purpuric manifestations are occasionally seen and a follicular papular eruption is recognized. The commonest and most vexatious mercurial cutaneous manifestation, however, is secondary to the irritation of inunctions, though intramuscularly injected mercurials may sometimes, even following the first administration, give rise to exfoliative dermatitis.

2. Mercurial stomatitis, probably the most common complication, is marked by more pronounced salivation than occurs with bismuth and by a less conspicuous tendency to pigmentation and discoloration of the gum margin. The lividity and edema of the mucous membranes due to the vasodilation, and the imprinting of the teeth indentations upon the margin of the tongue with an early tendency to the formation of leukocytic pellicles, are familiar characteristics. Fetor is pronounced but usually follows rather than precedes the development of marked stomatitis. The development of extensive necroses and tissue destruction suggesting Vincent's infection and agranulocytosis is less marked in our experience than with bismuth. Mercurial stomatitis is to an extraordinary degree amenable to the prophylactic control discussed under complications in Chapter IX.

3. Next in rank should be placed the gastro-intestinal reactions to the drug, conspicuous in mouth administration, often intractable and always to be avoided because once established they may constitute a permanent bar to the effective use of mercury in a given case. Mercurial diarrhea may follow suddenly on the injection of any intramuscular preparation and if a depot formation has developed may be so intractable that extreme degrees of emaciation and even death (as in the case of the gray oil) may ensue because the patient cannot be removed from the influence of the drug. Mercurial colic has been mentioned and may be an unmanageable contraindication to treatment. The abdominal pain may be so extreme that in combination with the meteorism frequently present it suggests intestinal obstruction or an acute abdomen. Gastro-intestinal complications, especially diarrhea, are favored by dietary irregularities, and especially by fruit and roughage, so that in the routine management of patients it is essential to inquire into and correct this point before concluding that mercury is not tolerated. Ulcerative colitis is a feature of severe mercurial intoxication.

4. Practically all mercurial therapy has a tendency to induce anemia through action on both the blood and bone marrow. While the drug has been called "the iron of syphilis," a certain degree of anemia is so universal a feature of effective therapeutic administration that the phrase bestows emphasis in the wrong place.

5. Mercurial rheumatism, the aches and pains, often with quite definite joint manifestations, associated with the intensive use of the drug, particularly by inunction, has its homologue in the bismuth grippe and may be so pronounced as to compel the suspension of the treatment.

Among the rarer manifestations should be included the effects of the drug on other mucous surfaces, including the induction of conjunctivitis, rhinitis,

intolerance to all the arsphenamines Bismuth preparations serve a particularly useful turn in the treatment of late neurosyphilis in which symptoms overshadow the serological findings. In the absence of the "red flag syndrome or preparetic spinal fluid formula and in the presence of pain, paresthesias and degrees of symptomatic disability and emaciation in which for one reason or another an arsphenamine is contraindicated, bismuth is superior to insoluble mercury or inunctions both on the score of absence of complications and positive therapeutic effects.

In dealing with the latent case in which after careful examination, only the necessity for maintaining the *status quo* becomes apparent, bismuth is again distinctly superior to mercury on the score of greater effectiveness and lower toxicity as well as a lessened likelihood of disturbing immunity balance through the use of the arsphenamines. None the less, in just such cases, regard for the waning but still significant worth of mercury calls for some division of the field between the two In the treatment of late syphilis with trivial manifestations, as for example, gummatous lesions in older individuals mercury by mouth or inunction is particularly useful because of its relative freedom from reaction producing qualities its therapeutic efficiency and its relatively painless administration.

Bismuth Shortcomings.—The weaknesses of bismuth have been repeatedly referred to The tendency to trust too much to it on account of its spirillicidal and healing power is a very serious matter in modern practice and justifies sharp criticism of some of its proponents, particularly among manufacturers of pharmaceuticals. Under no circumstances except those of an absolute intolerance should bismuth ever be used without an arsphenamine in the treatment of early syphilis, the practice of certain French authorities to the contrary notwithstanding. (See Chapter XIV on treatment of early syphilis.) In the treatment of syphilis of the liver and the heart, allusion has already been made to very clear-cut intimations of significant and dangerous therapeutic shock effects

MERCURY

Since the second edition of this work was published, mercury has definitely become syphilotherapeutic history Administered by mouth it still gives faint favorable therapeutic push, occasionally of use in old age and in the most ticklish and difficult of therapeutic shock situations By inunction it is still useful in hospital practice in isolated situations where patients must for months and even years, carry on a mild and safe treatment, free from risk of shock effect. reaction to treatment return t normal again if given sufficient time. Whether mercurial inunctions or intramuscular injections of mercury succinimide are given seems t make little difference in the time of ppearance or extent of renal irritation. The renal irritation resulting from combined arsphenamine and mercurial treatment is practically equivalent t the sum of that produced by the two drugs given separately Approximately one month is the proper time to allow for the urine to return t normal after stopping nonaccumulative mercurial treatment for syphilis. Patients with cord bladders under treatment for syphilis have very few casts in the urine, possibly due to disintegration but also perhaps to the fact that these patients kidneys seem less reactive than those of normal individuals and tolerate intensive treatment fairly ell. Patients who have damaged kidneys, as evidenced by chronic nephritis, nephrosis, focal nephritis and so forth show higher degree of reactivity t treatment than normal patients but recovery seems to be quite as satisfactory Reactions tend to become more severe as treatment progresses but if sufficient time for recuperation is allowed, repeated courses may be given, at least up to three or four without causing significant renal damage. Age as such is, moreover not contraindication to mercurial therapy from the standpoint of renal irritation. It is notable that spontaneous recovery from renal irritation may occur even in the face of continued administration of the drug, the kidney pparently acquiring tolerance

Mercury by Mouth.—Figure 81 is a thumbnail résumé in somewhat didactic form of the principle features of this mode of treatment.

Mercury by Inunction.—The inunction consists essentially of finely divided metallic mercury incorporated in a fatty base and rubbed into the skin, though at various times the substitution of insoluble salts such as calomel has been attempted in order to do away with the disagreeable color of the metallic preparation.

The distinctive qualities of the mercurial inunction are summarized in Fig 82.

The mode of absorption of the drug is via the respiratory tract secondarily and the skin primarily as shown by the studies of Welander and of Jenkins and Schamberg. The demonstration of globules of the drug in the skin about the hair follicles and sweat glands (Zwick) makes permissible the use of the so-called clean inunction in which the ointment remaining after vigorous rub is removed from the surface of the skin by fat-solvent such as benzine (Cole, Gericke, and Sollmann) Wile and Elliott have shown that mercury appears in the urine within twelve to twenty-four hours after its application to the skin. Saturation, however is slow according to Lomholt, and administration by mouth or preliminary intramuscular injection is permissible within the first tw weeks, which is as early as inunction therapeutic effects can be expected to develop Schamberg maintained that high proportions of calomel, over 50 per cent, may be used in inunctions effectively but Cole and Littman were unable to secure satisfactory evidence of its efficiency and most clinicians have discarded it.

The disadvantages of the inunction include particularly messiness, the possibility of betrayal a tendency to irritate sensitive skin and a ready onset of stomatitis if good mouth prophylaxis is neglected. Arsphenamine idiosyncrasy producing a tendency toward dermatitis, is a relative contraindication to the use of the inunction. Hairy patients develop intractable follicular irritation which may lead to mercurial dermatitis

Dosage Base Special Devices.—The official Unguentum hydrargyri (50 per cent metallic mercury) is satisfactory A tablet inunction of mercury in cocoa butter is cleaner and more easily rubbed in, and can be supplied in cakes containing 30 and 50 grains metallic mercury Measured dosage is extremely important and the infamous pea-sized inunction or amounts estimated as sufficient to go on a knife point, applied to the soles of the feet and small inconspicuous areas about the body have been responsible for much disappointment and disrepute for the inunction method. Four Gm. of the 50 per cent ointment weighed and dispensed in waxed paper or issued in capsules is the

average adult dose and 6 to 8 Gm. of the preparation (spoken of in case abstracts as "double-rubs) may be used in persons of large physique or for extremely intensive treatment.

The "course" of inunctions should rarely number less than forty taken at the rate of four to six rubs a week and more often the latter than the former The really extraordinary factor of safety in the mercurial inunction is testified to from an experience with more than 10 000 patients who have taken an aggregate of hundreds of thousands of rubs. Reasonably intelligent persons can be given as much as three courses of forty inunctions to be taken during the year and without other control than a careful instruction in mouth prophy-

Fig 82.

MERCURY BY INUNCTION IN SYPHILIS

1 The safest effective method of giving mercury but difficult to induce the patient to follow
2 The one really vailable method of effective self-medication in syphilis.
3. Valuable chiefly in institutional practice where its messiness is not objectionable, and in patients living alone
4 Avoids disturbance of the gastro-intestinal tract, but more readily induces salivation, hence insist on mouth prophylaxis.
5 The best tolerated of all mercurial treatment methods by the kidney
6. N cumulative effects.
7 Absorption is by the skin and respiratory tract.
8. A large area rubbed, energetic pplication, and warm room increase absorption.
9 Slow in getting into ction. T   eeks required for saturation.
10 Too slow for arsphenamine preparation in acut neurosyphilis and involvement of special sense organs.
11 Will not control contagious recurrence
12 Not sable on very hairy skins.
13 Provokes dermatitis in hypersensitive patients.
14 May precipitat a dermatitis in patients with arsphenamine idiosyncrasy
15 Overenergetic application favors complications.
16. T   hot baths nd sweat stop bsorption.
17 Underdosage is too often the rule One t 1½ drachms (4 to 6 Gm.) should be used with each inunction.
18. Use the 33 per cent strength of mercurial ointment when combined with arsphenamine If desired, 8 Gm. can be used. Fifty per cent strength is widely used.
19 Give rubs in courses of 40 t 80 six each week, with rest intervals of one t two months bet een courses. Three hundred is good total in early syphilis
20. Substitutes for metallic mercury in inunctions (calomel, etc.) are not gaining acceptance. Mercury oleate inunctions (15 Gm. of an ointment containing 1 Gm. mercury oleate) may be the exception (Sollmann *et al.*, 1935) These inunctions also have the advantage over metallic mercury of cleanliness, lack of detection, and greater ease of inunction.

laxis and occasional examinations of the urine can carry on their own treatment in conditions of relative poverty and isolation with a minimum of expense and with good therapeutic results as gauged by modern standards. Explicit directions to the patient go far to promote the effective use of the mercurial inunction and for that reason the instructions for taking rubs which are given in printed form to our patients are here reproduced verbatim (Fig 83) The clean inunction as devised by Cole Gericke and Sollmann differs from the general instructions in that the rubbing is carried out for thirty minutes by the clock, the area rubbed is at least eighteen inches in diameter the e cess ointment is wiped off with a soft cloth and the grayish stain on the kin re-

moved with a cotton pledget moistened with soap and water. The patient is permitted to change underwear and bedding whenever he desires, and to bathe. Absorption is from the follicles and the globules which have penetrated into the upper layers of the cutis. The fluidity of the mercurial globules is evidently important for pressing them into the follicles (Sollmann, Cole and Schreiber 1935). Cole, Rauschkolb, Schreiber and Sollmann have shown by careful elimination studies that it is possible to give mercury by massive

Fig. 83.

INSTRUCTIONS FOR TAKING "RUBS"

The medicine used in taking rubs enters the body through the skin. It must never be taken by mouth, or placed where children can reach it.

Rubs are taken in sets of six, one rub every night and a bath in place of a rub on the seventh night. Before rubbing, the skin where the rub is to be taken is to be thoroughly washed with soap and water and dried with alcohol intended for use on the skin. The rub is taken on one of six different places, a different place being used each night. The room in which the rub is taken should be warm.

1. The first rub is taken on the right-hand side of the chest in front of and below the armpit.

2. The second rub is taken on the left-hand side of the chest, in front of and below the armpit.

3. The third rub is taken on the right-hand side of the abdomen or on the flank.

4. The fourth rub is given on the left-hand side of the abdomen or on the flank.

If there is any hair on the outside of the thighs, the fifth or sixth rubs can usually be taken on the insides of the right and left thighs, respectively. Be careful not to rub where there is hair and do not rub two nights in succession on the same spot. If you are giving the rub to someone else, the back may be used for two or more rubs. Do not rub where there is hair or the skin will become inflamed. If there is much hair on the body call your physician's attention to it and ask him to tell you where to rub. Rub for at least twenty minutes *by the clock*. Rub firmly but not roughly. The skin should not be sore after the rub. Rub in a space of about a foot or 16 inches in diameter. Wipe off any ointment which remains on your hand on to the skin when you have finished.

Powder the skin after rubbing if you wish, but do not attempt to wash off or remove any of the ointment.

Through the entire series of six rubs the patient *should wear the same suit of underwear*. It is better to use old underwear which will become stained with the ointment. *Don't bathe during the series of six rubs* without special permission from your physician. After completing the series of six rubs, a bath should be taken on the seventh night in place of a rub. This bath should be with soap and hot water and all the grayish stain from the rubbings should be removed from the skin. The skin should then be powdered and the patient must change the underwear.

Rubs are usually given in sets of six and *the course of rubs consists of not less than forty*, covering a period of six or seven weeks. During such a course it is important that you should see your physician once in two weeks unless he allows a longer interval. Do not allow yourself to miss or skip rubs during a course without your physician's permission.

While this form of treatment is not pleasant, it is very effective and will do you much more good than the taking of pills or other medicine by mouth. For that reason you should persist in it as long as your physician thinks necessary, even though you may have to take a number of courses. Be sure to report to your doctor any trouble with the mouth or teeth. Your urine should be examined by a physician at least once in two weeks.

weekly inunctions to the body with 30 Gm. of the mild mercurial ointment U.S.P. without ill effects to the skin or other significant complications. A greater and more rapid cumulative excretion of mercury in the urine and an equal fecal output ensues, as compared with other methods of administration. The ointment was applied by two rubbers working for sixty minutes on each patient, and covering especially the chest, thighs, and forearms.

Belt Method.—Special methods for giving the inunction may be practiced in institutions, usually with the aid of masseurs. They are very effective in experienced hands. A belt for the

continuous administration of mercurial ointment percutaneously has been described by Wenge and its effectiveness under conditions involved in camps, penal practice and so forth, demonstrated. The belt is of rubber material 15 ½ inches, with a 3 ½ inch elastic tab t each end t permit fastening and freedom of movement. The belt is worn throughout the day carrying the day dose of mercurial ointment, and in the course of several hours the da dose is absorbed without interruption of the patient working activity The lif of the belt is between three and four months and the degree of bsorption secured is said t be efficacious nd t be demonstrated by the usual symptoms of mercurial saturation. Inquiries may be addressed t the Division of Venereal Diseases, U S Public Health Service Bethesda Station, W shington, D C.

MERCURY BY INTRAMUSCULAR INJECTION

The soluble salts of mercury in common use for intramuscular injection are the bichloride the succinimide and the benzoate. The insoluble preparations most widely used are mercuric salicylate the red mercuric iodide calomel metallic mercury finely divided in oil commonly spoken of as the "grav oil (Oleum cinereum) and certain colloidal preparations of mercury including most recently colloidal mercury sulphide.

Soluble Mercurial Salts.—Soluble mercurial salts are usually administered in aqueous or saline solution Their absorption is rapid and the therapeutic action of the simpler salts is prompt and noncumulative for relatively little of the drug is fixed as such in the injection site The use of glucose solution as a medium has recently been tried with apparently good results The incorporation of water-soluble mercurials in oily or fatty vehicles, precisely as in the case of bismuth markedly delays their absorption and reduces their effectiveness In order to secure good results from a soluble mercurial salt in aqueous solution, the injections must be given frequently daily or every second day and practically never less than once in three days. The injections have the reputation of being more painful than those of insoluble salts, but reaction is shorter-lived if more acute and is often a function of the salt used the concentration and the technic, rather than an intrinsic disadvantage in the method Under the competition of bismuth the soluble mercurial salts remain the only ones with the possible exception of colloidal mercury sulphide which the inexperienced practitioner can use with comparative safety to the patient and assurance of satisfactory and rapid effect. The soluble mercurial salt, as Lier noted a number of years ago, will dispose of infectious recurrences which have developed in the very midst of a course of inunctions or insoluble injections. The prolonged renal irritation and the gradual decline in vigor which patients treated with insoluble mercurial salts too often exhibit, we have practically never seen with a soluble salt. On the other hand there can be no denying the inconvenience of the daily injection and some patients are not so situated as to be able to accept it

Dosage, etc.—The bichloride of mercury and the succinimide are used in doses from ⅙ to ⅛ grain, four to six times weekly The solution can be made up in distilled water or physiologic saline in 30 cc quantities, kept in dark glass stoppered bottles 1 cc. of the solution representing the proper dose Larger quantities should not be made up at one time. The solutions are self sterilizing The succinimide is now marketed in this country in ampule form, with or without a local anesthetic such as butyn, and is very easily given, with almost no local reactions. The dosage of the red mercuric iodide and that of the benzoate is also ⅙ to ⅛ grain, three to five times weekly

A warning should be issued against the use of other tha glass containers for soluble mercurial salts. In dealing ith soluble mercurial salt it is also necessary t bear in mind the striking

and t times quit unaccountable variations in the behavior of different lots of supposedly pure soluble salts, which must be due t unknown chemical variations in composition or the presence of impurities.

Colloidal Mercurials.—The colloidal mercurials range all the w y from glucose suspensions of finely divided mercury which settle out on standing to the true colloid, such as the sulphide prepared and investigated in this country by Hille Wakerlin, reporting on the effectiveness of this drug in experimental animals, was very favorably impressed with it and Freeman, T ylor and White, using the drug in 25,000 injections in man, commented especially upon its serological good effects and its freedom from reaction. Lawless rates the drug as very effective mercurial by the intravenous rout especially albeit with definite renal toxicity

MERCURY ADMINISTERED INTRAVENOUSLY

Mercurial preparations can be administered intravenously as Baccelli demonstrated in 1893 and the fact that there is no corresponding safe route for the intravenous administration of bismuth will perhaps perpetuate for a time this otherwise unnecessary and esoteric method of using the drug

I cases in which it is considered absolutely essential t use mercury intravenously the oxy cyanide as the most familiar salt, is probably the best one to employ administered on dosage scale of 0.2 mg per kilo, or 12 mg. for the average adult dose.

Colloidal mercury sulphide introduced by Hille is stabilized in colloidal solution by hydrolized protein nd according to Gennerich is well tolerated when given intravenously and exerts surpassing mercurial action. It is especially effective against the positive W ssermann reaction but its clinical action is definitely inferior t the arsenicals. This drug is given in dosage of 2 to 3 cc. twice eek and may be safely administered continuously for series of 30 to 60 injections. Care must be exerted to void extravascular deposition of the drug, which produces lasting pigmentation of the skin.

The Action of Mercury on Syphilids.—The disappearance of spirochetes from primary and secondary syphilids treated with various mercurials varies from forty-eight hours to more than thirty-one days. (Ingraham, 1937) Given by mouth the rate of involution of the primary lesion and of secondary eruptions is only a little faster than their spontaneous resolution in the course of the disease Late manifestations, especially when iodide is given simultaneously sometimes respond with extraordinary rapidity considering the mildness of the measures employed. A rather extensive gumma of the forehead, for example, may disappear in three to six weeks. Mercury by inunction in spite of its greater intensity sometimes does not seem to secure more rapid healing effect than mixed treatment by mouth, so far as external lesions are concerned. There is a lag of at least two weeks in most cases before the beginnings of a real mercurial effect can be seen under inunction treatment. The soluble mercurial salts such as the succinimide however give rise to very rapid responses, a severe and extensive neuroretinitis, for example with hemorrhage and exudate, involuting completely in the course of fifteen to twenty daily injections, a rate hardly to be exceeded by bismuth or the arsphenamines. Similarly condylomatous lesions at the anus can be made to disappear in from seven to fifteen days the organisms vanishing before the fifth or sixth day Five to six weeks must be allowed for the resolution of a palmar syphilid under that most potent mercurial, the gray oil or calomel intramuscularly

Nonspecific Effects of Mercury—The use of blue ointment as inunction for the local treatment of periosteal lesions in bone has been familiar orthopedic practice Choroiditis of nonspecific origin will respond to mercury succinimide almost as rapidly t times, as t an arsphenamine. Even lupus vulgaris of the ulcerative type will mak some degree of improvement under

soluble mercurial salt and the mycoses and other granulomatous processes likewise at times show striking responses. On the other hand, in our experience, tuberculids, particularly the papulonecrotic type, d not d ell under mercury possibly because of its unfavorable effect in stirring up focal infections especially about the mouth and teeth. The nonspecific action of mercury with chalk by mouth is pronounced in such conditions as rosacea, which are associated with marked abnormalities of intestinal flora and hence improve under local antiputrefactive drugs. Mercury with chalk, for instance, is valuable in pruritus ani, very possibly for this same reason—namely its elimination at the seat of chronic infection. Mercury protiodide by mouth has been said by Whit Fox and others t influence favorably the course of verruca plana or flat warts.

Therapeutic Shock and Paradox.—The original observations of the Jarisch Herxheimer phenomenon were of course made on patients receiving mercury intramuscularly It is therefore apparent that it shares with arsphenamine and bismuth the ability to induce therapeutic shock. For this reason all initial dosage of mercurials should be reduced both to determine the tolerance of the patient for the drug and to avoid local flare-ups On the other hand the local shock effect is trifling with mercury as compared with arsphenamine and bismuth and this makes the drug under suitable conditions of dosage the *ideal* one for the introduction of treatment when shock effects are to be avoided. Mercury by inunction in particular is the most serviceable mode of administration where anything suggesting a Herxheimer effect must be avoided. The technic of preparation with heavy metal to avoid arsphenamine therapeutic shock effects will be presently discussed.

Other Heavy Metals

Extensive investigations conducted by Levaditi and Nicolau and their coworkers, including Fournier and Guénot, by Versari, by Proescher Seil, and Stilliams, by Jahnel (1928), by Klauder Vignati and Beinhauer and Jacob, have finally clarified quit definitely the question of the value of other metals chemically related to arsenic and bismuth in the treatment of experimental and human syphilis. The situation may be summarized by saying that mercury bismuth, tellurium, vanadium, platinum and gold are the only metals now definitely known to have antisyphilitic action.

N appreciator of the history of syphilis ould feel content with presentation of non specific therapy that did not mention the famous Zittmann decoction. This formula has sustained number of modifications, the basis of all of which is sarsaparilla. Perutz rates this one of the nonspecific modes of treating the disease comparable t the action of nonspecific protein and other forms of Reiz or shock therapy The active principle seems to be saponin in both this and the guaiac therapy

The Iodides

Historical Considerations.—Martin of Lubeck is credited ith the first administration of iodine in 1821 in the form of burnt sponge for the treatment of venereal ulcers of the throat The potassium salt as first employed by Wallace of Dublin in 1834 and it indications and contraindications pointed out. It has always been favorite with the French school of syphilologists and ttained under their influence recognized place in the treatment of the disease which in the American offshoot of French syphilology has amounted t perhaps at times an exaggeration of its importance in the treatment of the disease. Of lat German revival of nonspecific therapy for syphilis has brought various iodide derivatives t the front in the literature

The action of iodides is more completely nonspecific than that of any other commonly used standard medicament in syphilis. Nichols showed that in tolerated doses the drug has no spirillicidal action. It does not apparently influence the blood Wassermann reaction to any definable extent, but it does *assist materially in the resolution of granulomatous tissue* Pearce finds evidence of beneficial effect on systemic syphilis in the rabbit, especially when given in small doses over a long period of time

The action of the iodine radicle in the body is evidently matter of much complexity and it remains to be seen whether its influence on the metabolism as controlled by the thyroid gland, and thus on the general resistance of the patient t infection, has any special bearing on the action of the drug in syphilis. The theory of Jobling and Peterson, while not perhaps fully confirmed as yet, offers the best combined explanation of the local and systemic effects of the drug. These authors consider that the iodine radicle combines ith the unsaturated lipoids of the blood and tissues, thus inhibiting the action of the ntitryptic or antiproteolytic ferments which nor mally prevent utolysis. This inhibition of ntiferment permits the digestion of the tissues in which it occurs, with the disappearance of the digested tissue and its replacement by scar The selection of diseased tissue as site of deposit for unusual amounts of the iodine introduced is responsible for the seemingly specific selective action on granuloma, and is chemically demonstrable according t these uthors, in both tuberculosis and syphilis.

Inasmuch as iodides exert no spirillicidal action and do not, like mercury stimulate a specific cellular resistance mechanism against *Spirochaeta pallida*, they remain merely an adjunct to treatment, whose value is undoubted but also somewhat undefined.

Iodine is administered conventionally in the form of the iodides of sodium or of potassium. Small amounts of the drug may be introduced by inunction in oily bases, but no advantages are apparent to compensate for the smallness of the dose Certain organic iodine preparations (e g Siomine N.N.R.) are sometimes useful in patients intolerant of the inorganic iodides. Both sodium and potassium salts are rapidly absorbed when administered by mouth or rectum, and the sodium salt may be given intravenously in large doses though this mode of administration, like iodide therapy in general has been largely displaced by other more directly efficient methods

The following summary of the pharmacology of the iodides is abstracted from the extensive ork of E. D Osborne (1922).

Ninety-six per cent of iodine ingested is bsorbed from the gastrointestinal tract regardless of the dose (up to 20 Gm.) Within ninety-six hours practically the entire amount is liminated, also regardless of the dose, so that there is no evidence of cumulative action on the part of the iodides, as distinguished from mercury or the arsphenamines. Practically the entire amount of iodine administered, regardless of the route is eliminated through the kidneys, negligible quantities appearing in the stool even after diarrhea following very large doses. There is no evidence that the amount of urine excreted influences the amount of iodine excreted, and there are no urinary signs of iodine irritation. There is no difference between the rat of elimination when the drugs are given before or after meals, and, in fact, Osborne advises administration thirty minutes before meals because of the diminished gastric irritation. There appears also to be no advantage in the coincident administration of fats such as milk.

There is no advantage in administering small doses (2 to 5 Gm.) of sodium iodide intravenously unless the drug is given simultaneously by mouth.

A dose of 5 Gm of either sodium or potassium iodide three times day by mouth will maintain concentration of 20 to 40 mg. of iodine for each 100 cc. of blood serum for ten to twelve hours. This is equivalent to the concentration maintained for short time by 10 Gm. daily of sodium iodide intravenously thus being the average tolerated adult dose for the intravenous route. The iodine content of the blood serum following the intravenous injection of 10 Gm. of sodium iodide in 10 per cent solution rises to peak of 45 mg. per 100 cc. t the end of the first hour and drops rapidly until at the end of twenty-four hours it has fallen to 7 mg.

The concentration of iodine in the spinal fluid, of interest in the treatment of neurosyphilis, was likewise studied by Osborne. The issue is, of course, of special importance with reference to the securing of better penetration of the meninges by the drug following intravenous as contrasted with mouth or rectal administration. Osborne, working with sodium iodide, showed that while there was distinct variation in different individuals, and markedly greater increase in concentration in patients with active meningeal neurosyphilis, there was in general definite superiority in intravenous injection as compared ith other routes, in increasing the iodine content of the spinal fluid. There were also indications that neurosyphilitic tissue takes up more iodine than normal tissue in the nervous system. The curve of excretion from the spinal fluid parallels that in the blood

Clinically we may say that sodium iodide by mouth is regarded as less effective and is likewise less irritating to the gastro-intestinal tract than potassium iodide by the same route. The physiologic basis for this has been demonstrated by Osborne It is, however definitely better tolerated by mouth than potassium iodide in patients who show an idiosyncrasy Rectal administration is practically superfluous except in rare instances in which intravenous iodide is not available and mouth administration impossible The intravenous administration of sodium iodide is often well borne by patients who are subject to gastro-intestinal reaction. It is a method for securing a high concentration of the drug in the blood-stream for a short time and for

Fig. 81.

THE THERAPEUTIC USE OF IODIDE IN SYPHILIS

1 Highly nonspecific. Do not use for therapeutic tests.
2 A resolver of granulomatous processes.
3. A stimulator of resistance in prolonged small-dose administration.
4 The familiar concomitant and synergist of mercury
5. Useful where early syphilids, including the indurated chancre resist treatment.
6. Appropriate in large doses in all active neurosyphilis, including early symptomatic, diffuse, meningeal, meningovascular vascular and gummatous lesions.
7 Most useful in moderate doses in visceral syphilis.
8. Valuable in all forms of syphilitic cardiovascular disease small to moderate doses.
9 Effective in small doses in cutaneous late syphilis.
10 Use in prenatal syphilis as in late acquired syphilis.
11. Useless in syphilis of the pregnant woman for protection of the child.
12. Excellent interim treatment between other courses in serologically resistant cases.
13. Advocated for "loosening up" entrenched processes.
14 Small doses, 5 to 15 grains daily; moderate doses, 30 to 100 grains daily large doses, 150 to 1800 grains daily
15. Intravenous injection of sodium iodide may be useful in neurosyphilis; seldom required elsewhere Give 30 to 150 grains (2 to 10 Gm.) per dose, 3 to 5 times a week in addition to iodide by mouth.

Iodide ought not to be a stop-gap; it is not a spirillicide it is not specific. Yet, if no contra-indication appears, and in doubt whether to give it or not, better give it.

securing a maximum penetration of the nervous system. It should not be used for the administration of small doses (less than 7 to 10 Gm daily) potassium iodide by mouth producing as good results.

Toxicology of Iodides.—Iodides have in general so low a toxicity that there need be no fear of damage to vital structures by their intensive use in the overwhelming majority of cases. In fact the tolerated dose even in clinical practice is unbelievably large reaching at times in the therapy of blastomycosis 1500 grains a day On the other hand it is never possible to predict when iodide idiosyncrasy of a grave type may be encountered so that it is wise to make the first dose given a small one as Col. Harrison points out (*i. e.*, 5 grains) The recognized reactions include the syndrome of "iodism" including a catarrh of the mucous membranes in mild cases, and severe edema of the larynx in critical cases gastro-intestinal disturbances ranging from a brassy taste in the mouth produced by the excretion of the drug in the saliva, to anorexia nausea vomiting intestinal cramps and diarrhea iodide "mumps" an aching sensation at the angles of the jaw (Moore) and cutaneous reactions, including iodide acne erythema multiforme angioneurotic edema fungous,

vegetative, and frambesiform eruptions (Fig 85) acute bullous iodism and exfoliative dermatitis similar to that produced by arsphenamine and occasionally by mercury Recently febrile reactions, sometimes severe, have been reported following the use of iodides (Katzenstein 1938, Barker and Wood 1940) Stewart and Smith (1941) demonstrated changes in the electrocardiogram and in the cardiac rhythm during the therapeutic use of potassium salts and they advise careful supervision in the use of potassium iodide in the treatment of syphilis if toxic effects on the heart are to be recognized and avoided

Underlying all these reactions except the gastro-intestinal is a definite strain of idiosyncrasy which suggests some decided change in the colloidal balance of the tissues of susceptible persons. Bruck early investigated the mechanism of iodide idiosyncrasy and believed that he had demonstrated its transmissibility t animals through the medium of the serum, parenterally injected,

Fig. 85.—Frambesiform and vegetative type of iodide eruption.

of the susceptible person, but critical analysis of the work in the light of better modern conceptions of anaphylaxis and sensitivity lays its authenticity open to question. Wile, Wright, and Smith conclude that bacteria are not the sole cause of iodide and bromide eruptions, and that these eruptions cannot be classified as true sensitization phenomena as yet.

There is, of course, striking resemblance between certain of the cutaneous eruptions of iodism and those of bromism, in which the irritative effect of the drug perhaps lays the tissues open to the action of pyogenic micro-organisms. This may explain the bromide and iodide acnes and the fungoid and frambesiform lesions, but the fulminating erythema and edema that come on acutely after an intravenous injection, and the angioneurotic edema partake more of the character of vascular injuries Acute bullous iodism, fortunately very rare, is fulminating and fatal complication, with enormous bullous lesions appearing on base suggestive of an erythema multiforme with purpura. The exfoliative dermatitis of iodine idiosyncrasy may come on following the external application of iodine for disinfection or the use of iodoform, but we have never seen it follow the internal administration of iodides either by mouth or intravenously

There is an interesting difference between the effect of small and of large doses of iodides, which deserves experimental study Small doses seem more likely to give rise to coryza and acne than large doses. It has been not uncommon experience with the drug to see all signs of an annoying iodism disappear after the dosage passed 30 grains t. i. d by mouth. Patients who start with 30 grains seem less likely to develop signs of idiosyncrasy than those who start with 5 grains.

On the other hand, some patients develop gastro-intestinal intolerance on the higher doses, illustrating the difference between a sensitization and purely local irritative reaction.

Iodide by Mouth.—The potassium salt is in general the more satisfactory Two schools of therapy exist with reference to the dosage to be used. One group defends the small dose of 5 to 10 grains t. i. d., and the other advises a dosage of from 25 to 100 grains t. i. d or more. There is no experimental basis for either viewpoint as yet, beyond Pearce's observation of the resistance-stimulating effect of small doses in rabbits and the increase in iodine content of the blood with increasing doses observed by Osborne Clinically small doses of iodide seem able to hasten the resolution of syphilitic granulomata in the skin and bones almost as well as large doses. On the other hand, in such granulomas as that of blastomycosis the larger the dose, the better the effect. In the treatment of actinomycosis very large doses sometimes seem less effective than moderate doses. We have personally inclined in treating neurosyphilis to a dosage of 25 to 100 grains of potassium iodide three times a day The dose is usually made ascending, in the belief that there is an increase in tolerance thus obtained. A 1 1 aqueous solution in distilled water should be used (not a saturated solution) so that 1 minim equals 1 grain of the drug, and measurement with a minim glass or a dropper is usually desirable. The solution turns brown on exposure to light (free iodine) but is not necessarily spoiled. It should be kept in a dark place If difficulty is persistently experienced in attempting to use smaller ascending doses, an abrupt jump to 30 or 40 grains t. i. d. may overcome the idiosyncrasy Dosage may be increased by 1 to 5 grains daily thus meaning as must be carefully explained to patients, that each day's increase is to be taken three times during the day not added on to each succeeding dose. When the maximum is reached the dose should be held at that point until the necessary amount is taken, not decreased gradually to the starting point. Dilution markedly increases the tolerance of the iodides and doses of 50 grains should never be taken in less than a glass of water 100 grains in 2 glasses, 150 grains in 3 glasses. Milk is unnecessary except in infancy and childhood. The drug should be taken *before* and not after meals, to favor its early escape from the stomach. In patients who are markedly intolerant of iodide by mouth it is at times possible to give very large doses by putting the entire amount for the day in a gallon and a half of water and having the patient drink it in lieu of other beverage during the day Col. Harrison suggests the taking of the day's allotment in a single dose as effective For the brassy taste in the mouth little can be done but most patients soon grow accustomed to it. Rinsing the mouth with an aromatic wash (liq antisepticus alkalinus) just after taking the dose and before eating helps some patients to forget the annoyance Patients who have a marked gastric intolerance can often take sodium iodide intravenously without reaction. This is *not* true of patients with marked iodism and idiosyncrasy however The iodide eruptions should be watched for and the drug discontinued if any signs of the more serious types appear The acne often responds to a reduction of carbohydrates in the diet and the use locally of Lotio alba. The involution of fungoid iodide lesions may be hastened by wet dressings of potassium permanganate An attempt to demonstrate a specific cutaneous sensitively in one case of this type was successful controls of sodium bromide and sodium chloride solution being negative. It should be remembered that nursing women excrete iodide in the milk and that the child may therefore react sometimes violently

Sodium Iodide Intravenously.—With the development of fever therapy and fever-chemotherapy sodium iodide intravenously has ceased to be an important item in the treatment of neurosyphilis. To save space the description of its use, which involves a number of significant technical points, is omitted from this edition. A 10 per cent solution in distilled water sterilized by boiling for ten minutes and administered with every precaution employed in the use of the arsphenamines is the basis for the technic. The maximum dose is ten Gm. once a day. Its use should be preceded by a two-day tolerance test of the drug by mouth, 20 grains of potassium iodide t. i. d.

Contraindications to Iodide.—One definite contraindication to the indiscriminate use of iodide in the treatment of syphilis in addition to idiosyncrasy must be borne in mind. The drug should not be given to patients with thyroid adenomas. We have seen several serious examples of adenomas being made toxic in this way. Tuberculosis is a conventionally accepted contraindication. Iodide is sometimes blamed for serious acute edema in laryngeal disease and Henck advises against it in nephritis with concentrated urine. Klauder and Vandoren (1941) believe that the iodides unfavorably influence the final visual acuity in both active and inactive interstitial keratitis.

The Technic of Heavy Metal Preparatory Treatment

The Importance of Preparation.—The technic of heavy metal preparatory treatment for the avoidance of therapeutic shock will be repeatedly referred to in subsequent chapters. It is therefore here described and merely referred to again under the prevention of complications. The fresher the infection, the younger and more robust the patient, and the more clearly it can be demonstrated by careful and complete examination, including serological tests of the spinal fluid, that no critical form of involvement or disease of a vital structure exists, the less necessary is preparatory treatment for the use of the arsphenamines. On the other hand, so rarely are these conditions fulfilled in average clinical practice, especially in latent and late phases of the disease, and so difficult is it with the relatively coarse methods available in most medical examinations to detect minute but extremely important foci that preparatory treatment is justifiably important in the protection of the patient against that large group of complications classifiable under therapeutic shock or Herxheimer effect. The use of the heavy metals because of their slower action as compared with the arsphenamines is not an absolute necessity, for increasing exploration of the field of small-dosage arsphenamine therapy tends to indicate as in the Kothny Müller Deham technic for treating cardiovascular syphilis and our own experience with bismuth arsphenamine sulphonate (bismarsen) that minute ascending dosage of an arsenical can be made to take the place of the preliminary use of a heavy metal to a considerable extent. None the less, the physician called upon to treat syphilis with the knowledge of the present day will, we believe, feel safer if he adopts the general rule of limiting initial vigorous use of the arsphenamines to early syphilis and with the aid of bismuth protecting his patients from unpredictable explosive and destructive effects by preliminary heavy-metal treatment.

Preparatory Treatment in Early Syphilis.—Early in the course of a syphilitic infection, that is, within the first several weeks, warnings of risk of serious complications may be drawn from a history of severe or violent headaches or of visual or eighth nerve disturbances, particularly tinnitus and dizziness or jaundice. If any of these symptoms be definitely present, it is wiser to begin

the treatment of the patient with bismuth rather than arsphenamine postponing the latter drug until the symptoms are abated or investigation discloses their lack of significance for the disease. Often a spinal fluid examination may be necessary to establish this fact. After three to six weeks of bismuth therapy the patient may usually safely be placed upon an arsphenamine. If the symptoms, as for example, of a fulminating papillitis or neuroretinitis, are actually endangering the patient's vision, much more rapid effect can be secured by the daily injection of ⅙ to ¼ grain (0.01–0.016 Gm.) mercuric succinimide accompanied by large doses of iodide. This method of preparation is also usable in less pressing but definite complications originating in the nervous system. It need not usually be continued longer than two to four weeks, following which an arsphenamine may be employed. These statements should not be taken as authority for the neglect of the intensive use of arsphenamine in all phases of early syphilis in which no definite danger signs appear and care must be taken not to overestimate trifling complaints as an excuse for evading an intensive beginning of treatment for curative effect.

Preparatory Treatment in Late Syphilis.—In the later phases of the disease especially where it has been impossible to make a thoroughgoing examination, three forms of preparation are useful including (*a*) bismuth intramuscularly (*b*) mercurial inunctions (*c*) a soluble mercurial salt such as the succinimide intramuscularly. If anything approaching a rule of thumb may be proposed 20 to 30 injections of mercuric succinimide ⅙ to ¼ grain (0.01–0.016 Gm.) with liberal doses of iodide by mouth (50 to 100 grains t. i. d.) or sodium iodide intravenously constitutes the preferred treatment, when obtainable, for an acute neurosyphilis. Failing this, bismuth sodium tartrate may be given in doses of 2 cc. twice or even three times weekly but this alternative we regard as distinctly second best. Bismuth preparation in late syphilis with incomplete examination may be made with any one of the effective liposoluble salts or the oil-suspended bismuth salicylate four to twelve weeks being required under ordinary circumstances. In cardiovascular syphilis extremely small doses of bismuth or of bismuth arsphenamine sulphonate (bismarsen) not exceeding 5 mg. bismuth metal for the first several doses or 10 to 25 mg. of the bismuth arsphenamine sulphonate makes an excellent approach to more intensive treatment. In late hepatic syphilis, the mercurial inunction with moderate doses of iodide by mouth is still unsurpassed and patients should be urged to take this form of treatment from four weeks to three *months or even a year before an arsenical is considered.* *Observation of a* number of unfortunate and even disastrous end-results of haste and fast acting drugs in hepatic and cardiovascular syphilis have led us to return almost with enthusiasm to mercury and iodide. Even the initial administration of mercury by mouth may be necessary in properly grading the approach to more intensive treatment in syphilitic hepatic cirrhosis. These strictures placed upon the use of intensive modern methods in late syphilis should not, as has already been said, be allowed to veil or overshadow the tremendous importance of the initial use of the arsenicals in early syphilis in the absence of clear-cut contraindications. But just as a system for treatment to be used in early cases of syphilis should emphasize and depend on the arsenicals as a public health as well as therapeutic ideal so the system in late cases taught the average medical student must subordinate and defer the use of arsenicals since there is no infectiousness to control, in favor of the slower, safer preparatory treatment with bismuth or a mercurial.

CHAPTER VII

THE ARSENICALS—THEORETICAL AND PRACTICAL CONSIDERATIONS

The Field of Arsenotherapy.—"Arsenic" has come to imply a species of art-magic in the mind of the medical profession whenever the therapy of syphilis is considered so that the first word of a discussion of the arsenical phase of treatment must be one of caution. The combinations in which arsenic is involved in the chemotherapy of syphilis are fully as important to the behavior of a drug which contains it as is the arsenic radicle itself. Moreover the valence of the arsenic is of the greatest importance and trivalent as distinguished from pentavalent arsenic is essential to the spirillicidal action of the arsenicals used in the treatment of syphilis. Trivalent arsenic has dominated the scene since 1910 but the growing importance of the pentavalent group merits extended discussion. Into the development of the trivalent arsenicals is crowded one of the fascinating romances of medical history and both for its perspective-giving value in a comprehension of this enormously important group of drugs as well as for its worth as an exemplar of human progress an historical summary seems in order.

The Trivalent Arsenicals—Historical Considerations.—The arsphenamines which constitute the outstanding modern representative of the group of trivalent arsenicals are the products of dye chemistry fired by the genius of Ehrlich—a biologist who well illustrates how great men are so often made by combinations of aptitude and circumstance. A lifelong familiarity with the processes of body metabolism and particularly with the oxidation-reduction chemistry of living cells combined in him with an acquaintance with the chemistry of dyes and a coincident knowledge of parasitology to provide the foundation for an extraordinary theoretical vision. As a piece of constructive thinking, the synthesis of the arsphenamines is an astonishing and epochal achievement. To it, however, as to most great consummations, many men contributed. Laveran and Mesnil, through their studies of the *Trypanosoma equiperum* and their development of a controllable mouse technic, contributed the organism that was to form the base for the chemotherapeutic contact with disease. Shiga, and Von Weinberg, working with Ehrlich, identified the first trypanocidal effect of a dye of the benzopurpurin group, and took the first step in rational synthesis by introducing sulphogroups into the compound to form a soluble product with markedly increased trypanocidal effects. This was the dye Trypan Red with which modern trypanocidal chemotherapy began. Laveran and Mesnil introduced arsenic into the problem. Atoxyl, the first chemotherapeutic compound to receive extended trial in man, only to be subsequently abandoned because of its relatively frequent induction of optic atrophy, came on the stage with the work of Béchamp (1863) and later of Landsberger and Blumenthal. The efforts of Thomas and of Breinl and Kinghorn to apply atoxyl to human trypanosomiasis therapy attracted Ehrlich's attention to the drug and Uhlenhuth, Gross and Bickel showed it to be active against the spirochetosis of hens. Thereupon Ehrlich, working with the chemist Bertheim in a lifelong association which led directly to the synthesis of the arsphenamines, treated atoxyl with nitrous acid, obtaining a diazo-like dye-forming compound that upset all previous notions of the constitution of atoxyl and provided the key to the future chemistry of the arsphenamines in the so-called arsanilic acid. By successive steps the panorama was unrolled; the vital importance of the amino group in further synthesis was demonstrated together with the recognition of the body's intervention in the production of parasiticidal action by reduction of pentavalent to trivalent arsenic, a process that does not occur in the test tube. These genuinely inspirational conceptions were the direct outcome of previous unrelated studies by Ehrlich of the oxygen requirements of the body. Ehrlich

concluded as his experience increased that to secure maximum spirillicidal efficiency the reduction must be performed for the body not by it.

Next, utilizing an observation from his experience with azo dyes, Ehrlich grasped the importance of the ortho position of hydroxyl and amino groups in producing trypanocidal drugs. The aminophenylarsenic acids followed and then by another reduction with sodium hydrosulphite, the arsphenamine base and its dihydrochloride the 606th of a series of compounds elaborated by Ehrlich and his coworkers. The halogen plays an essential rôle even in this drug, so generally thought and spoken of by the physicians who use it and its derivatives, as "arsenic.

The intricacy of the intramolecular chemistry of these dyes is illustrated by the statement of Raiziss and Gavron that the ortho position of the amino radical is essential that in this position, nitro and methyl groups depress the therapeutic activity of the drug: that iodine introduced *into the arsphenamine base removes the trypanocidal effect while it greatly increases the spirillicidal action.* The approach to exact predictability is suggested by the fact that the introduction of two or more amino groups into the arsphenamine base increases the toxicity 20 per cent, while the therapeutic dose remains the same. A substitution in the amino group of the arsphenamine base reduces the toxicity 40 per cent, as in neoarsphenamine, but the minimum therapeutic dose is increased from 23 mg. per kilo in arsphenamine to 40 mg. per kilo in the case of neoarsphenamine, or 10 per cent. It is on the gradual working out of laws such as these governing the behavior of the various radicles involved, as Raiziss and Gavron remarked, that the further advance of chemotherapeutics depends.

Clinical Introduction of "606."—The preliminary tests of "606" on man were made under the direction of Alt, two of whose assistants, Hoppe and Wittneben, volunteered for the first doses intramuscularly N ill effects ensuing, it was used in the treatment of several syphilitic imbeciles, and then, for the first time, in the clinic. The drug, Salvarsan (606) was announced by Ehrlich and Hata before the Medical Association of Magdeburg on March 5, 1910. On December 14 1910, after thousands of doses sent to clinicians *gratis* throughout the world had proved the worth of the drug, it was placed on the market. Stokes recalls the whispered accounts of the amounts of morphine required by the two physicians receiving the first intramuscular doses at Ann Arbor The impossibility of the intramuscular procedure from the practical standpoint, with its pain, sloughs and prolonged encapsulation, led to Ehrlich reluctant acceptance of intravenous administration as developed by Schreiber and by Hoppe and Iverson, for which he predicted reduced therapeutic effectiveness. It is indeed far cry from the suit-case full of burets, tubing and reagents and the surgical ceremonial of the first intravenous injection, t the "hit-run, syringe-and-ampule, shot giving technic of the war days and after

The deluge of press publicity the captivation of medical thought by phrase, the fading of the Ehrlich dream of sterilization by single dose (*therapia sterilisans magna*) under the reports of relapse notably those of Finger on neurorecurrence are really only minor incidents in triumph of constructive thinking that within one decade raised empirical medicine and rule-of-thumb syphilology if only in as yet incompletely fulfilled promise, to the dignity of an exact science.

The Modern Arsenicals.—The subsequent development of other arsphenamines and the revival of arsenoxide has been beset with many difficulties Neoarsphenamine the sulphoxylate compound and the 914th member of the series has demonstrated if nothing else, the vast importance of technical simplification and elimination of inconvenience and discomfort for the patient, in the practical adoption of an idea by the medical profession. The First World War was literally won syphilologically speaking, on the syringe technic for neoarsphenamine devised by Ravaut. The second will perhaps be won on the simplifications of arsenoxide. A superior drug, arsphenamine proper or 606 is passing into the discard because it is difficult for the average doctor to give The distinctive contributions of later years have been silver arsphenamine (Karrer Kolle) sulpharsphenamine (Voegtlin) identical with myosalvarsan (Kolle) bismuth arsphenamine sulphonate (Raiziss) the two latter intended for intramuscular use, both for technical reasons and in the effort to restore the Ehrlich tradition of intramuscular superiority In the past decade beginning with the work of Tatum and Cooper (1932 1934) and continued by numerous other investigators favorable results have been reported from the clinical use of the hemialcoholate of 3-amino-4 hydroxyphenylarsine oxide

hydrochloride (mapharsen) This preparation and 3-amino-4-hydroxyphenyl dichloro-arsine hydrochloride (dichlorophenarsine hydrochloride, phenarsine hydrochloride, clorarsen) used in the long standard systems or in foreshortened treatment are now dominating the investigative field

It required the disrupting forces of the First W to release the study and fabrication of the arsphenamine group of drugs from the German control of patents, with the initiation of American manufacture by Schamberg Kolmer and Raiziss. Forthwith, each nation adopted a terminology of its own for its own products, including Kharsivan, arsenobenzene diarsenol, and so forth salvarsan remains the German designation for the group, and arsphenamine (ars-phen-a-meen) the official and now widely used American term. Arsenobenzol is probably the generic international term.

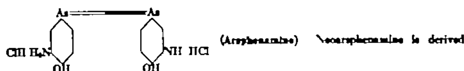
Toxicity Controls and Choice of Product.—The toxicity controls for different nations vary but the underlying principles have been described. In the United States they are in the hands of the National Institute of Health of the United States Public Health Service. International conferences have resulted in greater uniformity of practice (League of Nations Health Organization, 1925 1928) Regulation could be materially extended by utilizing known facts on perishability and variability of lots through a system of dating plus an effort at therapeutic standardization based on spirillicidal rather than trypanocidal action. The difficulties, however are considerable If an arsphenamine "misbehaves," the physician, after a rigorous inquiry into his own technic, should send duplicate samples of two ampules each from the offending lot (see control number on ampule) to the manufacturer and to the National Institute of Health, United States Public Health Service, Bethesda Station, Washington D C., with a full statement. Government control at first withheld has now been extended to mapharsen. The pentavalent arsenicals (tryparsamide) are not controlled.

The question frequently asked by the practicing physician as to which arsphenamine is best among a number of manufacturers products can be honestly answered at the present day in this country by the statement that all arsenicals subjected to Government control and of a well-known standardized type are, like all automobiles of responsible manufacture, good.

Miscellaneous Nonspirillicidal Arsenicals.—A deluge of preparations capitalizing the concept of "arsenic as an antisyphilitic agent without regard to chemical constitution or serious investigation of claims, has flooded the market since "606. It must not be imagined that because drug is an organic arsenic synthetic or because it merely contains arsenic, that it has any value whatever in the treatment of syphilis. Arsenical tonic effects re good enough in their place, and obtainable with variety of preparations such as the cacodylate, arsenious acid, and so forth, but they have no place hatever in the treatment of syphilis by the use of spirillicides. "Monarson, "Venarsen, and similar preparations have nothing in common except the syllable ars with the modern arsphenamine therapy of syphilis. The practicing physician should therefore select his arsenical armamentarium with reference to syphilis on the basis of careful study of authoritative orks and the practice of well-organized schools and clinics, rather than from the advertising pages of journals in these days of pharmaceutical enterprise.

The Arsphenamine Discard.—It is inevitable that experimental chemotherapy will give birth to preparations of only ephemeral value or inevitably and naturally replaced by others of superior merit. The slow process of evaluation will inevitably compel many frank revaluations and many reversals of opinion. Among the drugs hich have reached or are approaching eclipse may be mentioned silvarsan sodium, or neutral arsphenamine, the sodium salt of the arsphenamine base neosilverarsphenamine, rated by Raiziss as one-half as toxic as silver arsphenamine and slightly more toxic than neoarsphenamine galyl" (Mouneyrat 1116), phosphoarsphenamine of French origin very popular during the first orld war but with no demonstrated advantages and supposed sodium salt of this drug hich is in reality nothing more than an illustration of the chemical legerdemain which lies between the paper constitution of synthetic arsenical

concluded as his experience increased that to secure maximum spirillicidal efficiency the reduction must be performed for the body not by it.

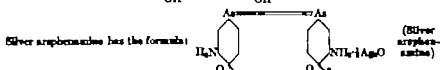


Next, utilizing an observation from his experience with azo dyes, Ehrlich grasped the importance of the ortho position of hydroxyl and amino groups in producing trypanocidal drugs. The aminophenylarsenic acids followed and then by another reduction with sodium hydrosulphite, the arsphenamin base and its dihydrochloride, the 606th of series of compounds elaborated by Ehrlich and his coworkers. The halogen plays an essential rôle even in this drug, so generally thought and spoken of by the physicians who use it and its derivatives, as "arsenic.

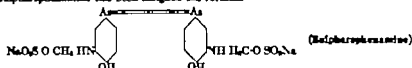
The intricacy of the intramolecular chemistry of these dyes is illustrated by the statement of Raiziss and Gavron that the ortho position of the amino radical is essential that in this position, nitro and methyl groups depress the therapeutic activity of the drug that iodine introduced *into the arsphenamine base removes the trypanocidal effect while it greatly increases the spirillicidal action.* The pproach to exact predictability is suggested by the fact that the introduction of two or more amino groups into the arsphenamine base increases the toxicity 30 per cent, while the therapeutic dose remains the same. A substitution in the amino group of the arsphenamine base reduces the toxicity 40 per cent, as in neoarsphenamine, but the minimum therapeutic dose is increased from 25 mg. per kilo in arsphenamine to 40 mg. per kilo in the case of neoarsphenamine, or 16 per cent. It is on the gradual working out of laws such as these governing the behavior of the various radicles involved, as Raiziss and Gavron remarked, that the further advance of chemotherapeutics depends.

Clinical Introduction of "606."—The preliminary tests of "606" on man were made under the direction of Alt, two of whose assistants, Hoppe and Wiltneben, volunteered for the first doses intramuscularly N ill effects ensuing, it was used in the treatment of several syphilitic imbeciles, and then, for the first time, in the clinic. The drug, Salvarsan (606) was announced by *Ehrlich and Hata before the Medical Association of Magdeburg on March 3, 1910. On December* 14 1910, after thousands of doses sent to clinicians *gratis* throughout the world had proved the worth of the drug, it was placed on the market. Stokes recalls the whispered accounts of the amounts of morphine required by the two physicians receiving the first intramuscular doses at Ann Arbor The impossibility of the intramuscular procedure from the practical standpoint, with its pain, sloughs and prolonged encapsulation, led to Ehrlich reluctant acceptance of intravenous administration as developed by Schreiber and by Hoppe and Iverson, for which he predicted reduced therapeutic effectiveness. It is indeed far cry from the suit-case full of burets, tubing and reagents and the surgical ceremonial of the first intravenous injection, to the "hit-run, syringe-and-ampule, shot giving technic of the war days and after

The deluge of press publicity the captivation of medical thought by phrase, the fading of the Ehrlich dream of sterilization by angle dose (*therapia sterilisans magna*) under the reports of relapse, notably those of Finger on neurorecurrence are really only minor incidents in triumph of constructive thinking that within one decade raised empirical medicine and rule-of-thumb syphilology if only in as yet incompletely fulfilled promise, to the dignity of an exact science.

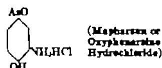


The Modern Arsenicals.—The subsequent development of other arsphenamines and the revival of arsenoxide has been beset with many difficulties Neoarsphenamine the sulphoxylate compound and the 914th member of the series has demonstrated if nothing else the vast importance of technical simplification and elimination of inconvenience and discomfort for the patient, in the practical adoption of an idea by the medical profession. The First World War was literally won syphilologically speaking, on the syringe technic for neoarsphenamine devised by Ravaut. The second will perhaps be won on the simplifications of arsenoxide. A superior drug arsphenamine proper or "606" is passing into the discard because it is difficult for the average doctor to give The distinctive contributions of later years have been silver arsphenamine (Karrer Kolle) sulpharsphenamine (Voegtlin) identical with myosalvarsan (Kolle) bismuth arsphenamine sulphonate (Raiziss) the two latter intended for intramuscular use both for technical reasons and in the effort to restore the Ehrlich tradition of intramuscular superiority In the past decade, beginning with the work of Tatum and Cooper (1932, 1934) and continued by numerous other investigators, favorable results have been reported from the clinical use of the hemialcoholate of 3-amino-4 hydroxyphenylarsine oxide

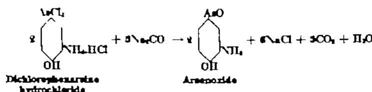


Neoarsphenamine is derived from the arsphenamine base by the substitution of sodium monomethylene sulphonat group attached to one and also to part of the second amino radical. Its formula (approximate) is as follows (after Voegtlin)

Silver arsphenamine has the formula:



and sulpharsphenamine has been assigned the formula



Bismuth arsphenamine sulphonate is a compound of sulpharsphenamine and bismuth.

Mapharsen is the trivalent arsenical which is the hydrochloride of meta-amino-para-hydroxy-phenylarsine oxide. It is obtained from alcohol ether solution in the form of hemi-alcoholat which is a white fluffy hygroscopic powder. It contains 29 per cent arsenic in trivalent form. In the dry state it is stable but in contact with air and moisture it gradually darkens. The name, mapharsen, has been constructed from the chemical term. Structurally it is represented by the formula,

Dichlorophenarsine hydrochloride, 3-amino-4-hydroxyphenyl dichloro-arsine hydrochloride (dichlorophenarsine hydrochloride, clorarsen, phenarsine hydrochloride), is a trivalent arsenical preparation containing 26 per cent arsenic which is available on the market with sufficient alkaline buffering agent (sodium citrate or sodium carbonate) to make neutral prepared solution for injection. On the addition of sterile distilled water to an ampule containing the mixture of dry dichlorophenarsine hydrochloride and alkaline buffer a reaction takes place with the result that arsenoxide is formed. This reaction is represented as follows:

Preparation of Arsenicals for Administration.—All the arsphenamines are yellow powders with the exception of silver arsphenamine, which is brown and yields a brown solution. The aqueous solution of "606" is strongly acid and

the solubility of the drug is less than that of any of the other derivatives, formerly requiring hot water to put it into solution. The acid solution of arsphenamine "606" cannot be injected intravenously in any considerable concentration without the most disastrous results. In order to prepare the solution for administration it must be neutralized by the addition of normal sodium hydroxide which first of all precipitates the insoluble base as a yellowish white precipitate. As a further addition of the alkali takes place this yellowish white precipitate of the arsphenamine base redissolves as a monosodium salt. This in turn, on still further addition of the alkali, is converted into the still soluble disodium salt of the arsphenamine base, yielding a canary yellow solution with a pH of from 9 to 10 Only in this form and in the proper dilution can the drug be safely injected into the blood, though the monosodium salt or a mixture of mono- and disodium salts can be injected under proper precautions by those experienced in its use.

The arsphenamine disodium salt solutions are hemolytic in all concentrations. One of the chief sources of acut nitritoid reaction t the drug has been show by the excellent work of Oliver and his collaborators to be the tendency of the disodium salt to agglutinate red blood cells This can be overcome to some extent by buffering the solutions with gelatin, method that has not, however gained foothold in practice In our personal experience the original technic of preparing arsphenamine solutions under proper precautions with 0.6 per cent physiologic saline has distinct advantages on the score of reduced reactivity and better tolerance by the veins. The question as to the relative safety and merit of mixtures of monosodium and disodium salts as compared with the disodium salt alone is debatable.

Neoarsphenamine and the other widely used derivatives escape the serious and sometimes tragic defect of requiring neutralization for their safe administration. This neutral reaction in solution by simplifying the administration technic with a lower tendency to immediate reaction, undoubtedly accounts for their vastly greater popularity in practice. Neoarsphenamine as a powder and in solution is a distinctly darker yellow than "606" and manufacturers have prided themselves on the development of what is called flash-solubility" or almost instantaneous solution of the drug in water at room temperature. This characteristic, which sharply differentiates neoarsphenamine in the process of preparation in the treatment room from the much slower-dissolving arsphenamine while useful, is rather overstressed in salesmanship It is none the less true that neoarsphenamine that will not immediately go into solution in 10 cc. of water at room temperature may present serious defects and should be discarded. Sulpharsphenamine is dissolved in 2 cc. of water silver arsphenamine and mapharsen, like neoarsphenamine in 10 cc. of water and bismuth arsphenamine sulphonate in 1 cc of water for the accustomed therapeutic dose

The arsenical content of the arsphenamines is very variable but is pproximately as follow Arsphenamine (606) 30 per cent neoarsphenamine (914) 19 per cent, sulpharsphenamine 19 to 20 per cent silver arsphenamine 12 to 14 per cent silver and 19 t 20 per cent arsenic; mapharsen 29 per cent; bismuth arsphenamine sulphonate, 21 per cent bismuth, 13 per cent arsenic. While it is easily possible from these figures t obtain the arsenical content in milligrams of each dose of an arsphenamine that is given, it should be fully realized that no such method of estimating the therapeutic dosage of arsphenamine compounds is satisfactory because the therapeutic effect is, as has already been emphasized, dependent upon many other considerations besides the arsenic content. Thus, as ill presently be pointed out, the arsenical content of tryparsamide is approximately equal t that of "606" but its spirochetocidal properties are negligible notwithstanding its effectiveness in penetration of the nervous sy tem and treatment of paretic neurosyphilis. Within given group, however Voegtlin et al. have show that the sterilizing power of massive dose of arsphenamine neoarsphenamine or sulpharsphenamine in the rabbit i precisely equiva-

lent to the arsenical content, which is the same in all three instances, regardless of the difference in the dose of the compound administered and regardless of whether it is given in one dose or divided among series (Voegtlin, *et al.*)

Preparation of Arsenoxid (Mapharsen) for Administration.—Mapharsen in the ampule should be a whit crystalline powder and if color changes have occurred, it should be discarded It goes into solution readily in 10 cc. of water and in contrast to neoarsphenamine, aeration by the bubbling of the solution and the squirting of the solution back and forth by the syringe is method of releasing toxicity For clinical use mapharsen, according to the manufacturer's directions, is supplied mixed with sufficient amount of alkali and sucrose to make the aqueous solution practically neutral and isotonic with the blood Again in contrast t neoarsphenamine, the mapharsen solution should be administered rapidly instead of slowly; again from the directions, "the time elapsing from the insertion of the needle until the syringe has been emptied and the needle removed from the vein should be no more than thirty seconds.

The Biological Chemistry of the Arsenicals.—The arsphenamines, whether injected intravenously or intramuscularly are taken up by the blood stream and are carried to all the tissues of the body The distribution of arsenical drugs to tissues differs in the case of organic as compared with inorganic compounds. Underhill and Dimick, working with dogs showed that the quantity present in the tissues did not necessarily depend on the amount given or on the number of injections. A sharp line is thus to be drawn between administration and penetration and still another line can be drawn as Osborne and his co-workers have suggested between penetration and metabolizing of an arsenical drug

Work on the presence and distribution of arsenic in the circulation of the body tissues has been serious field of controversy now it is to be hoped, about to be resolved by the use of radioactive arsenic as foreshadowed by the recent studies of duPont and her associates (1942) of the distribution of the tagged atom in the normal and tumor-bearing rabbit. Riebes early showed that arsphenamine as such is present in the blood about three hours, but might persist for longer periods in patients who react. Fordyce, Rosen and Myers found marked difference between patients in their disposal of injected arsphenamine, permitting definite classification of patients into two groups—those who retain and those who rapidly eliminate arsenic. On the average, they found 60 per cent of the arsenic administered in an intravenous injection of neoarsphenamine to be localized outside the blood-stream by the time the injection is completed. The controversy regarding differences in localization of trivalen and pentavalent arsenicals with particular reference to the blood-vessel walls, has involved the work of Osborne, using microchemical method of Justus and observers like Tannenholz and Muir (1933) and Oppenheim and Fantl (1934) who were unable to confirm Osborne findings. There are many reasons, both clinical and chemical for suspecting that the arsphenamines are vasculotoxic, an extremely important fact in their reaction-producing characteristics and their therapeutic effect. Chaney and Magnusson (1940) have proposed colorimetric microchemical method for determination of arsenic which may overcome some of the inherent difficulties. Osborne has proposed that the pentavalent arsenicals are to be regarded as neurotropic and the trivalent as vasculotropic.

Notwithstanding the inherent difficulties of chemical analyses for arsenic, fair and indeed, the best available picture by the older procedures, of the distribution of arsenic in the body following the injection of arsphenamine, is given in Figure 86. Following the administration of the arsphenamines, arsenic also appears in the perspiration (Ullmann), saliva (Obregia and Carnol) vomitus, probably due to regurgitation of bile from the duodenum (Weiss and Raiziss), and the milk of lactating women. With the trivalent arsenicals, the nervous system contains only very minute amounts of arsenic, for which Schamberg proposed the view that the easy penetration of serous membrane by crystalline pentavalent arsenicals permitted concentration of arsenic in the nervous system of these drugs, and corresponding failure to penetrat on the part of the colloidal trivalent arsenical preparations.

Arsenical Penetration under Fever and in Pregnancy—Paulian and Tanasescu (1936, 1937) found that the concentration of neoarsphenamine in the cerebrospinal fluid was greater when the drug as given simultaneously with malaria. This has been denied by Hällstrung and Nordmeyer who concluded that salvarsan as such does not pass into the cerebrospinal fluid, even under favorable conditions as afforded by artificial fever therapy It is probable that salvarsan, being colloid, does not pass the blood-cerebrospinal fluid barrier but passes through the blood-brain

barrier where it exerts its beneficial effect on the diseased nerve tissue. Recent studies show that placental transmission of the arsenicals varies with the stage of pregnancy, the rate of transmission increasing as pregnancy progresses (Eastman and Dippel, 1933, Snyder and Speert, 1938).

Storage of the Arsphenamines.—In the practical use of the arsphenamines it must then be constantly borne in mind that while their accumulation at the site of injection is nil in the case of the intravenous route, and comparatively small or absent in the case of the better absorbed arsphenamines such as neoarsphenamine and sulpharsphenamine, a very real and sometimes serious degree of storage may occur in the liver and spleen, and in the walls of the intestinal tract. Underhill and Dimick found the largest amount of arsenic present in the kidneys, following neoarsphenamine in the dog, but the time after injection and similar factors undoubtedly influence this finding because of the function of the kidney as an eliminative mechanism. There is very little doubt that the distribution of the drug is modified by circumstances not as yet understood and that, as Fordyce wrote and Myers has suggested, individuals may be grouped into

Fig. 86.

ARSENIC CONTENT OF TISSUES, ETC., FOLLOWING ARSPHENAMIN INJECTION

Tissue analyzed.	Normal Arsenic Content.	Voegtlin et al. micromilligrams after 100 min.	Clausen and Jeans milligrams As_2O_3 per 100 gms. after twenty four hours.
Heart	0.50	2.83	0.0025
Spinal fluid	0.69	7.21	
Brain	0.08	1.16	0.0
Skeletal muscle	0.03	0.38	0.0
Lungs	1.91	3.93	0.275
Blood	0.29	5.23	
Spleen	5.53	16.83	0.67
Kidney	0.42	2.58	0.154
Urine	2.66	19.62	0.341
Liver	0.55	16.17	0.830
Bile	1.12	196.54	
Stomach			0.151
Stomach wall	0.36	1.03	
Stomach content	0.11	12.36	
Intestinal tract and content	0.07	6.96	
Duodenum and part of jejunum			0.370
Lower ileum			0.306
Rectum and colon			0.380
Skin	0.20	1.60	
Adrenals			0.0
Bone-marrow			0.0
Embryo		0.22	

two or more types with respect to elimination and so also perhaps in regard to storage. Osborne and coworkers have shown that arsenic is not stored in the adrenals of the rabbit, the damage done by the drug probably being due to vascular injury.

Elimination of the Arsphenamines.—As in the case of the heavy metals, the therapeutic efficiency of an arsenical in the treatment of syphilis is to no small extent a function of its rate of elimination. Within the limits of toxicity there occurs an optimum curve of elimination. If elimination is greatly delayed, toxic effects develop. If it is too rapid, therapeutic effect may conceivably be lessened. Wide individual variations exist here as in storage and metabolism, a fact sufficiently apparent from the conflicting reports of investigators. In the elimination of the drug by way of the urine and feces, which constitute the two important routes, the amounts present are independent of the amount of either excrement but apparently depend on the concentration of arsenic in the blood. A series of injections, according to Underhill and Davis, stepped up the rate of elimination of the drug, which explains the clinical fact that patients given large doses at short intervals may tolerate a longer series than patients receiving smaller doses at longer inter-

vals. The maximum excretion is said to occur on the first and second days after the administration and not on the day the injection is given. Small amounts of arsenic are gradually eliminated over a period of many weeks, the total of this retained arsenic aggregating sometimes 50 per cent of the whole dose (Clausen and Jeans) The partition of the eliminated drug between stools and urine varies with the type of drug given and the number of injections, Underhill and Davis stating that after a series of injections the rate of elimination in the stools is more rapid than in the urine although the arsenic appears later in the stools than in the urine at the start. Clausen and Jeans placed the rate of elimination by the stool as five times as rapid as that by the urine. This is in accordance with Voegtlin's finding of a relatively large proportion of the injected drug in the bile Underhill and Davis believe that they find evidence of a saturation point of the tissues for arsenic comparable to that for heavy metals and suggest the propriety of large initial and smaller later dosage in the majority of cases.

Importance of the Liver.—According to the studies of Kraft and his coworkers (1938) the organ predominantly concerned in the immediate removal of arsenic from the blood stream and its excretion is the liver The intestines and kidneys follow in order The total arsenic in these organs decreases steadily and after two days the intestinal mucosae contain as much as the liver The concentration of arsenic was highest in the spleen during the first hour This organ is the only one which showed a tendency to "fix" arsenic. The other organs usually showed a decrease in concentration. The kidneys generally showed a higher concentration than the liver These studies indicated that, while it does not occur greater quantities of arsenic can be excreted in the urine than in the feces.

Applying considerations with reference to elimination to the conditions of clinical practice one finds in them a justification of the empirical practice of giving a cathartic the day after an arsphenamine administration Differences between the arsphenamines on the score of renal irritation-producing effect, while seldom of great importance clinically will probably tend to follow the rule that neoarsphenamine is more irritating to the kidney than arsphenamine The nonirritating effect of the arsphenamines on the kidney as compared with heavy metals is both clinically and experimentally demonstrated A field of clinical study with important possibilities would seem to be that of the application of test procedures to the presence of arsphenamine in the blood and urine for the purpose of detecting abnormal retention, and hence of storage by the liver and other tissues. For this purpose the Abelin test is sometimes used. (See M C S., Ed II, p. 296) See also duPont, *et al.* (1942) p 237

Mode of Action of the Arsphenamines.—Although the as yet unconfirmed work of Eagle and his associates (1938–1939) (*vide supra*) suggests a direct spirillicidal action for the arsenicals, there are a number of reasons for believing that the arsphenamines do not react directly and solely with the micro-organisms of syphilis, but that the effect is produced by their decomposition products. Foremost among the facts weakening the theory of direct action are the numerous observations beginning with those of Hata on the failure of arsphenamine solutions in concentrations as high as 1 to 1000 to affect either the motility or growth powers of *Spirochaeta pallida* and the demonstration of the "lag" in action of the arsphenamines after their introduction into the body For a period varying from five to eight hours no effect upon the *Spirochaeta pallida* is observable following an arsphenamine injection. Then, coincidently with the appearance of reactive symptoms in the patient, the organisms gradually disappear during the course of the next twelve to twenty-four hours.

The coincidence of reaction which reaches its peak at the 8th hour with the appearance of spirillicidal effect is very striking and strongly suggests that within the latent period one of two things has occurred either the bodily defence mechanisms has been stimulated with extraordinary

rapidity to produce antispirochetal substances of a wholly unknown organic nature, a colossal and almost universal phagocytosis by the reticulo-endothelial system is taking place; or the injected and now stored arsphenamine is being broken down into products having a more direct spirillicidal action than the injected drug itself. The decline in activity and viability of the *Spirochaeta pallida* during the succeeding hours after the fifth certainly suggests that all the work of destruction is not done by fixed cells but is carried on in part by a circulating destructive agent. The search, accordingly, should be for a product of the disintegration of arsphenamine having a high toxicity for the micro-organisms and capable, as in the case of the heavy metals, of being discharged into the circulation from storage depots in the body over a long period of time. A number of the requirements for this theoretical agent are fulfilled by the substance arsenoxide which is an oxidation product of the arsphenamine base. Arsenoxide is extremely poisonous in very high dilutions for trypanosomes in concentrations as high as one to a million.

In spite of the narrow margin of therapeutic and toxic effects of arsenoxide on the host predicated by the experience of Ehrlich and Voegtlin and confirmed by Raiziss and Severac (1935) the direct administration of arsenoxide following Tatum and Cooper by the Foersters, McIntosh, Wieder and Cooper has shown that meta-amino parahydroxyphenyl arsine oxide is a powerful, quick-acting spirillicide. The question as to whether its action is sufficiently sustained to control relapse and its toxicity especially for the liver still require further clinical investigation. Kolmer, Schamberg and Brown have shown that the oxidation of the arsphenamines on standing, yielding arsenoxide, greatly increases their spirillicidal effect.

It has been proposed that the action of the arsphenamines takes place through an arseno-protein combination and Levaditi in his studies of atoxyl proposed for this arsenical the formation of an intermediate compound, trypanotoxyl, the predecessor of his subsequent bismoxyl, as the active toxicological combination. There is no doubt that a certain amount of fixation of arsphenamines in blood corpuscles and serum takes place, and Ehrlich early showed that trypanosomes are likewise capable of fixing the arsphenamines with a loss of pathogenicity in the organisms. This, however, is believed by Voegtlin to be a less credible explanation than that of the direct interaction of the arsenoxide radicle with the sulphhydryl oxidation mechanism of the parasitic cell by way of oxidation-reduction catalysts such as glutathione.

Since Voegtlin, Dyer and Leonard (1923) advanced the hypothesis that sulfhydryl groups present in the protoplasm of the parasite take part in the reaction with the drug and hence should be considered as the "chemoreceptor" there seems to have been little attempt to prove this theory. In 1932 Rosenthal and Leonard, however, advanced further experimental evidence corroborating the previous findings concerning the antagonistic effect of thiol (sodium thioglycollate) compounds on the physiologic activity of organic arsenious oxides. Eagle (1939) contributed additional support to Voegtlin's thesis by showing that sulfhydryl compounds (cysteine, glutathione, and thioglycollic acid) added in sufficient excess to arsphenamine, neoarsphenamine, silver arsphenamine, arsenoxide, bismuth or mercury compounds almost completely abolish their antispirochetal activity in vitro. The large excess which is necessary suggests that the addition compound may be hydrolyzed. Thiamine chloride and methionine which contain a —S— rather than a —SH group have no inhibitory effect. Eagle recognizes the possibility that the spirocheticidal activity of the arsenicals, bismuth and mercury compounds may be due to a chemical reaction which bears no relationship to their affinity for and inactivation by sulfhydryl compounds.

It will be apparent from this highly condensed survey that the original Ehrlich receptor theories of the direct linkage of the arsphenamines with the parasites they attack have given way to more complex conceptions none of which may be said as yet to have received unqualified endorsement. In all probability, as in the case of the action of nonspecific protein and fever therapy, multiple modes of action are involved in which each proponent may claim a share for his particular conception. Tatum (personal communication to Moore 1942) and Simpson (1942) approaching from widely different angles, have well stated the problem in saying that it is not the quantitative arsenical content or location, but what the arsenic does when it reaches the spot which is important in its chemotherapeutic effect. Before the problem is worked out, not only the metabolism of chemotherapeutic compounds by the body but the metabolism of protozoa and spiral organisms must receive far more extended study.

THE PHARMACOLOGY AND TOXICOLOGY OF THE ARSPHENAMINES

When it is considered that the maximum adult dose of "600" and its congeners in therapeutic equivalents introduce into the body and usually directly into the blood stream something approximating twenty-six times the fatal dose of arsenic, the range in variety of toxicological manifestations produced by this group of drugs is quite to be expected and the wonder grows that with the thousands of doses given each day and the millions each year throughout the world the toll of grave damage and fatal outcome is not appalling instead of relatively trivial. While however the triviality is apparent in the aggregate, it disappears at once in the concrete and a physician, watching with perplexity and alarm the outcome of his "shot has good need of detailed knowledge as well as rule-of thumb in comprehending and dealing with an arsphenamine on the rampage

In order to make apparent the fundamental resemblances between the heavy metals especially bismuth and the arsphenamines, as well as to catalog for convenient reference the range of arsphenamine toxicological manifestations, we have prepared Fig. 87 which may well be compared with Fig 75 page 201 for bismuth. It will at once be apparent that while there is a general resemblance based on absorption and elimination phenomena, the greater solubility of arsphenamine compounds and the possibility of their direct introduction into the blood stream leads to a much larger proportion of vascular injury perhaps than occurs with the bismuth compounds, although vascular injury of a more chronic type is again important with mercury Like bismuth, the arsphenamines spare the kidney but to an even greater degree. The toxicity of an arsphenamine for the kidney has been rated by Schamberg, Kolmer and Raiziss as only one fiftieth that of mercury The disposition of the trivalent arsenicals to injure the vascular system affects every aspect of their reaction producing quality and must constantly be borne in mind in their therapeutic use, while the effect of these drugs on the kidney could were they used exclusively be almost forgotten

McFarland showed very clearly in his study of the behavior of the kidney under treatment for syphilis that in the mercurial days it as mercury which introduced all the renal complications into treatment with the single exception of the fulminating anuria that may follow the administration of an improperly neutralized "606"; and the same principle has been borne out in the American Cooperative Clinical Group study of complications under treatment for early syphilis. In this latter series of studies not only did the heavy metals as source of renal reactivity appear as of major importance, but the arsphenamines when used alone or with little heavy metal proved throughout the entire range of reactivity to be by far the most innocuous part of modern treatment for syphilis. This finding lends decided color to the generalization so frequently insisted upon by Schamberg, for example, that the toxicity of the heavy metals for the eliminative mechanism and particularly of mercury for the kidney gives rise to phenomena of arsenical intoxication through abnormal retention of the drug by an overloaded or injured eliminative mechanism. On the other hand, the resemblances between the types of reaction produced by arsphenamine and the heavy metals suggest that part of the increased reactivity under combined treatment may result, so to speak, from striking the same spot with two fists.

New Reaction Classification.—In our more recent discussion of arsenical reactions, we have tended to use a new type of classification, emphasizing the induction and incrimination of allergic factors in the arsenical-reactive picture, but especially conspicuous in the arsphenamines.

1 *Idiosyncratic Allergic Phenomena* —Hemorrhagic encephalopathy aplastic anemia most cases of exfoliative dermatitis.

TOXICOLOGY OF THE ARSENICALS IN MAN

I. **Local reactions at injection sites.**
   1 **Pain, induration, necrosis.** Most marked with "606, and arsenoxide (mapharsen) almost negligible with other arsenicals. Gangrene of hand due t neoarsphenamine or arsphenamine (Newman nd Giles; Sutter Oddo nd Giraud Schloffer) (intra-arterial injection? acid solution? arsenical endarteritis obliterans?).
   2. **Vein spasm.** Usually due to hyperalkalinity but rarely idiosyncratic and accompanied by local hemorrhagic injury
   3. **Venous thrombophlebitis.** Common with mapharsen if injected slowly
   4 **Abscess.** Rare

II. **Systemic Reactions.**
   1 **Vascular**
      ( ) **Nitritoid or vasomotor crisis** (especially after intravenous, but also intramuscular use) Due t agglutination of red blood cells (capillary emboli) (Oliver Douglas *et al.*) liver cell injury from rapid injection (Hirshfeld, Hyman nd Wanger) and other undefined causes. Rare after arsenoxide (marpharsen)
      (*b*) **'Colloidoclastic shock.** Collapse and death immediat or preceded by coma or convulsions, jaundice and nuria. Most often due to acid 606 (unneutralized) but may rarely be idiosyncratic
      (*c*) **Capillary and finer blood vessel injuries as in:**
         Hemorrhagic encephalopathy (edema and punctat hemorrhages of brain)
         Purpura haemorrhagica.
         Hypotension, collapse (possibly adrenal vascular injury—Osborne)
         Raynaud syndrome.
         Cutaneous injury (vascular factor in cutaneous eruptions, especially toxic erythema, urticaria, dermatitis (Osborne)
      (*d*) **Fatal medical shock** (Orr; Weinberg) shock-like reactions t the arsenicals, adrenal injury (?)
      ( ) **Acute interstitial myocarditis** (Brow and McNamara) associated with arsenical dermatitis (allergic.)
   2. **Stomatitis:** Rare, occasionally accompanying dermatitis and aplastic anemia. N pigment, fetor et
   3. **Gastro-intestinal tract** Vomiting, diarrhea rarely ulcerative colitis (ith dermatitis) Gastric ulcer perforation.
   4 **Nervous system** Rare peripheral neuritis (foot and wrist drop) polyneuritis. Optic nerve injury theoretical but unestablished. Arsenical myelitis. Encephalopathy Arsenical herpes. Nervous tension and insomnia.
   5 **Skin** Cutaneous allergy induced pruritus, urticaria; erythema multiforme macular papular morbilliform, scarlatiniform, pemphigoid fixed exanthem, arsenical (or silver) pigment and keratoses (rare); herpes (rare) lichenoid and follicular papular eruptions (pseudo-lichen planus); pityriasis rosea-like eczematoid patchy eruptions, dermatophytic flare-ups flare-ups of seborrhoeic dermatitis arsenical exfoliative dermatitis.
   6. **Liver** (rather rare) Acute arsphenamine jaundice (arsenical hepatitis) lat arsphenamine jaundice acut yellow trophy chronic arsenical hepatitis (Warthin) intercurrent infectious jaundice on predisposed arsenical-injury background.
   7 **Kidney** (rare) Treatment nephrosis anuria, usually after acid 606.
   8. **Adrenals** Direct or vascular with Addisonian symptoms, hypotension collapse A rare nd even doubtful reaction.
   9 **Respiratory system** Bronchitis (ith dermatitis) Bronchopneumonia after 606. Pulmonary embolism and subsequent bronchopneumonia from arsenicals, other than 606, if pH of solution is less than 7 (Shivers) Asthma (Klauder Saunders, 1932)
   10. **Joints** Arthritic reaction ith erythema multiforme
   11 **Blood** Hemolysis, agglutination (606, 914) agranulocytosis plastic anemia ith stomatitis and purpura (sulphoxylat arsphenamines, especially sulpharsphenamine)
   12. **Allergic reactions** Cutaneous, pulmonary vascular (nitritoid) as above included under various heads.
   13. **Therapeutic shock effects:** Not properly classifiable as arsphenamine reactions.

NOTE HOW MUCH ARSENIC AND BISMUTH HAVE IN COMMON

2. *Infection Allergic Phenomena*.—Milian ninth day erythema, some exfoliative dermatitis, urticaria, the intercurrent infection factor apparent in jaundice, and in the periodicity or wavelike character of other types of reaction.

3. *True Drug Reaction Phenomena*.—Arsenical hepatic atrophy, polyneuritis, true arsenical dermatitis, eczema and pigmentation, pigmentary and fixed eruption.

4. *Technical Reaction Phenomena*.—Nitritoid crisis, speed and colloidoclastic shock, gastro-intestinal reaction.

This classification lacks consistency in some points, in that nitritoid crisis, for example, contains allergic elements, and gastro-intestinal reaction may be true drug reaction rather than a technical matter. The classification, however, has suggestive value in the interpretation of interrelations between focal and intercurrent infection and reaction incidence and precipitation, and in explaining some of the sequences and characteristics of the more fatal reaction phenomena which appear to involve special structures like the capillary vascular system of the brain, the bone marrow, and so forth.

Arsphenamine Local Reactions.—The local reactions produced by the arsenicals are due fundamentally to arsenic and when leakage around an improperly entered vessel occurs in any considerable amount, the characteristic violent inflammatory reaction followed by the extraordinarily persistent arsenical slough may be expected. The alkalinity of solutions of "606" is possibly a contributing factor. In the more recent arsphenamines, however, such as sulpharsphenamine and bismuth arsphenamine sulphonate, local necrotic action has been reduced to the point where the drug is entirely tolerable and in fact rapidly absorbed. Abscesses are almost unknown with the less irritating drugs under aseptic technic. Vein spasm and venous thrombophlebitis are almost entirely confined to "606" and mapharsen. Thrombophlebitis has a distinct element of hypersensitivity though it is more often due to incorrect preparation of the solution with hyperalkalinization. Thrombophlebitic changes are apt to occur in any vessel showing repeated spasm and can be recognized by the cordlike feel under the finger at the next treatment session and history of tenderness or pain during the preceding week.

In the extremely rare cases of idiosyncratic local hemorrhagic injury, the slightest attempt to inject arsphenamine results in almost instantaneous spasm with violent pain, blanching of the surrounding skin and, if injection is persisted in, frequently by suggillation and hemorrhage, especially if the vessel be of small caliber. Thrombophlebitis promptly closes the vein. Newman and Giles (1940) have reviewed the subject of gangrene of the extremities due to arsenical injection. The exact mechanism of this effect is unknown.

Systemic Intoxicating Effects of the Arsphenamines—Vascular Injuries.—The effect of the arsenicals on the heart is discussed under Reactions (Chapter IX) and Cardiovascular Syphilis (Chapter XIX). The group of vascular injuries is one of fascinating interest and the acute vasomotor or vascular crisis spoken of as the nitritoid reaction has probably its best examples and has been most thoroughly studied in the field of arsphenamine therapy. The identical reaction may occasionally occur after bismuth injections and such nonspecific treatment as the intramuscular administration of boiled milk. Nitritoid reactions occur after all of the arsphenamines, most frequently after "606," rarely but none the less definitely after the intramuscular drugs and almost never with mapharsen. The clinical aspects of the reaction are described in detail on page 409.

The Nitritoid Reaction.—This still remains a puzzle notwithstanding the long history of competent investigation, for which, to save space reference is made to the second edition of this text. A variety of considerations point to an anaphylactic or anaphylactoid mechanism tied in with the rate of administration of the drug, and probably associated with the complexity of the molecule and the colloidal character of the solution since such reactions are almost completely absent with mapharsen, notwithstanding its rapid rate of injection. The influence of atropin in protecting against reaction, the possibility of inducing Besredka-like phenomenon of protection by a preliminary small dose, the intravascular agglutination of red blood cells (Oliver Douglas and Yamada) are suggestive of this type of mechanism. There is evidence of a distinct idiosyncratic quality to the reaction in certain patients, of its gradual development in a manner comparable to sensitization by repeated assault, and in the clinical symptomatology which is in some particulars quite comparable to anaphylactic shock. Hirshfeld, Hyman and Wanger in their studies of so-called "speed shock," have related the mechanism to injury inflicted on the liver cell as a function of the rate of introduction of the offending substance. It is also possible that some of the symptoms may be due to the liberation of histamine or histamine-like substances into the blood-stream under the influence of the drug as in Sir Thomas Lewis' explanation of anaphylactic phenomena. We have had occasion to suspect strongly on clinical grounds that the sympathetic nervous system participates in nitritoid types of reaction and shock, and they have seemed more common in individuals with sympathicotonic characteristics and an intense nervous anxiety. While intrinsically of little more than subjective importance as a highly disagreeable episode for the patient, easily developing or frequently recurring nitritoid crisis may be interpreted as a warning of possible serious vascular dysfunction or injury.

Colloidoclastic Shock.—This reaction produced by the arsphenamines is a function of their colloidal behavior in solution presumably and in its most severe form is a fulminating and fatal affair. Colloidoclastic changes, of course, inevitably follow the injection of acid "606," especially in any considerable concentration, and it is this which is responsible every year for fatalities in clinics and practice which should be preventable. If the patient's life is not immediately extinguished by the shock, a period of coma or convulsions preceded by agonizing pain in the kidney region and followed by anuria and perhaps jaundice declares the profound and probably arsenical character of the intoxication. On the other hand, these incidents are at times apparently absolutely idiosyncratic. Fortunately they are very rare. Colloidoclastic shock is apparently identical with "medical shock" following neoarsphenamine, as discussed by Orr (1933) and Weinberg (1937). Adrenalin does not relieve the condition.

Other Types of Capillary Injury—Hemorrhagic Encephalopathy.—The other types of capillary and finer blood vessel injury associated with the arsenicals again have the quality of extreme gravity. Hemorrhagic encephalopathy, also called "brain purpura" and arsphenamine encephalopathy, more fully described under Reactions (p. 434) is an acute edema of the brain with innumerable capillary hemorrhages throughout its substance, and is a chief cause of death from the arsphenamines. Glaser and the Imermans have pointed out that the reaction occurs in nonsyphilitic persons, apparently without relation to age or sex, or to the dosage of the drug administered, the number of injections given, or to the intrinsic toxicity of the preparation. The reaction occurs most commonly after the second dose, may develop within twelve hours or after a latent period as long as several days. The autopsy picture in the brain is that of dilatation and engorgement of meningeal and cerebral vessels with a picture suggesting "wet brain," plus vascular necrosis and perivascular hemorrhage of the "ringed" type. It may occur with or without universal purpuric accompaniments, the patient, after a brief period of mental confusion lapsing into coma punctuated by convulsions and in the large majority of cases terminating in exitus. The resemblance of the edema to that associated with delirium tremens has been pointed out.

The hypotension which frequently follows arsphenamine administration in reacting patients is theoretically related to the adrenal mechanism because of its response to epinephrin and ephedrin. In a patient with the Addisonian syndrome associated with syphilis, one of us (J. H. S.) was able after each

arsphenamine injection to watch the course of the vasomotor collapse and slow recovery after arsphenamine very much more marked than in any patient previously observed and accompanied by a deepening in pigmentation, extreme weakness and diarrhea. This was in the prebismuth days.

Osborne's investigations certainly suggest that a large part of the cutaneous injury produced by the trivalent arsenicals is associated with damage to the capillaries, in whose walls extensive deposits of arsenic can be demonstrated to the exclusion of other skin structures, which are more apt to be affected by the pentavalent arsenicals. Presumably this factor operates likewise in the erythema multiforme groups of vascular injury.

Injuries to the Gastro-intestinal Tract.—Those inflicted by the arsphenamines tend to be acute, soon over and rarely serious. They are least frequent with mapharsen. Stomatitis, so characteristic of the heavy metals, is an extreme rarity under the arsphenamines, being as often though not necessarily an accompaniment of exfoliative dermatitis, in which the inflammatory process seems to involve the mouth together with the gastro-intestinal and respiratory tracts, and aplastic anemia, in which there is probably no direct causal relation except the underlying arsenical intoxication. Pigment, fetor and so forth do not occur in arsphenamine stomatitis and in fact the ability of these drugs to contribute to the sterilization of the mouth with respect to saprophytic and especially Vincent's flora, makes them have actual prophylactic value in dealing with heavy metal stomatitis.

The reactions of the upper gastro-intestinal tract are probably associated with the elimination of the arsphenamines through the bile as they are metabolized in the liver. On the other hand, the lower intestinal tract exhibits, as Osborne has shown, marked deposition of arsenic in the mucosa and muscular layers (there is also some deposition in the walls of the upper intestinal tract) and this, as in the case of bismuth, explains the more serious symptoms, including ulceration of the colon which may accompany profound arsenical intoxications with and without dermatitis. The damage done to the gastro-intestinal tract by arsenic is perhaps contributory to the perforation of gastric ulcers occasionally observed under arsphenamine treatment even though marked vomiting has not occurred.

Injuries to the Nervous System.—The relative rarity of other than vascular lesions of the nervous system among arsphenamine reactions is notable. Peripheral neuritis, heralded by tingling, and much more leisurely in its onset than that characteristic of lead, for example, occasionally occurs under high dosage arsphenamine treatment, especially among the first cases treated by massive arsenotherapy. Polyneuritis is a not uncommon accompaniment of severe intoxication; arsenical myelitis occurs in conjunction with intraspinal therapy rather than otherwise where the drug is brought into direct contact with nervous tissue, and arsenical herpes zoster occurs as in other forms of chronic arsenical poisoning. The arsphenamines give rise to what will be subsequently alluded to as an "overtreatment syndrome" of nervous tension and insomnia comparable to the effects of bismuth therapy on certain individuals. Encephalitis should be regarded as a vascular reaction rather than one involving the nervous parenchyma as such.

Injuries to the Skin.—The cutaneous toxicology of the trivalent arsenicals (including mapharsen) has practically the same range as bismuth but a distinctly greater frequency and graver character. The simplest reaction, pruritus, may occur alone and repeatedly but is usually a warning of something more

serious to come. Together with urticaria and exfoliative dermatitis it may form part of the expression of the true cutaneous allergy which has now been shown both clinically and experimentally to be produced by drugs of the arsphenamine series. This phase of arsphenamine toxicology is considered separately below. The erythema multiforme types of reaction are usually sharper than those observed with bismuth and probably express the vascular injury produced by the drug plus its influence as suggested by Milian in activating or lighting up foci of infection containing streptococci such as are known to be associated with this type of reaction in patients not receiving treatment for syphilis (see Ninth Day Erythema, page 419). The arsphenamine fixed exanthem is an eruption of peculiar interest in that it is of a type known to occur also with drugs of the antipyrin type and likewise with phenolphthalein (Chargin and Leifer 1940). The recurrence of urticarial lesions *in situ* over and over with successive administrations of the drug until the two or three individual areas involved become lichenified and to some extent eczematous is a clinical phenomenon wholly without basic explanation. Atrophic changes may also occur (poikiloderma-like changes Cannon *et al* 1942), reticular fibro-atrophoderma following arsphenamine dermatitis (Epstein 1938). Pigmentation and keratoses are fortunately rare complications. Pigmentation from silver arsphenamine has been reported by Kogoj and recently in the American literature by Spiegel and by Becker and Ritchie *et al*. The distribution of arsenic has been studied by Osborne. Vitiligo has been extensively studied by Cannon and Karelitz (1933). Herpes is a rarity and may be both of the simple and zoster type. The simulation of lichen planus by the lichenoid arsenical eruption is so exact that in view of the developing conceptions of lichen planus (see p 552) as an associate of sympathetic nervous system disorders, it seems not improbable that a similar nervous mechanism may be involved in arsphenamine lichen planus. Peripheral gangrene and Raynaud's syndrome have been reported by Nicolas, Massia and Dupasquier (*vide supra*). The ability of the arsphenamines, probably through their arsenical content, to influence other dermatoses occasionally gives rise to false impressions. For example a pityriasis rosea-like exanthem may occur particularly with bismuth arsphenamine sulphonate as with bismuth; patchy eczematoid eruptions are well recognized as associated with arsenic and sometimes difficult of diagnosis. Flareups of seborrheic, mycotic and occasionally pyogenic processes, have been noted by Lees, Harrison and Smith (1938). Stokes and Kulchar have discussed the infection allergic implications. One of the most interesting and confusing of these pictures is the flare-up of inguinal and peri anal dermatophytosis with the appearance of patches on the body that is not infrequently confused by the inexperienced with a relapsing secondary syphilid. We have seen at least half a dozen such cases in consultation in which the physician feared he was dealing with an arsenic-fast syphilitic recurrence.

Arsenical exfoliative dermatitis is the arsenical cutaneous *bête noire* with its former 50 per cent mortality. As a clinical entity this is subsequently discussed in greater detail from the standpoint of diagnosis and treatment, but has an as yet incompletely elucidated etiology.

It is particularly true of arsphenamine cutaneous reactions and especially exfoliative dermatitis that they have a systemic background of predisposing causes, one or more of which may contribute to the production of the trouble which is provoked into explosion by the exciting cause. Among the predisposing factors must be enumerated various causes of vascular injury of the vari

ous types described heretofore which may form the anatomicopathologic basis of the arsphenamine urticarias erythema multiforme and ninth day erythema as well as dermatitis storage overload as when the skin receives an unduly large share of arsenic owing either to perverted metabolism of the drug or subnormality of the other storage depots cutaneous physiologic or functional abnormalities, such a those present in seborrhea (hypersecretion of fat) true allergies to arsphenamine a tendency to allergic reaction to irritants constituting the eczematous diathesis the sensitizing influence of circulating bacterial protein or split products from acute or chronic infection the effects of hepatic injury and possibly as Moore has suggested bone marrow injury which lowers the resistance of the patient to infections and influences hi tolerance of drugs.

Theoretical discussions ill be found in Schiff Moore and Keidel, nd Stokes and Cathcart, but are too long for full citation here In general it may be said that the major theories group themselves int allergic, infection, and arsenical schools. Cathcart and Stokes felt that the allergy as not necessarily specific for arsphenamine but recognized it as the basic fact. Moore and Keidel suggested the allergy-inducing effect of colloidal solutions of the drug. Klauder Frei, Sulzberger and others have independently demonstrated the allergy-inducing and skin-sensitizing properties of the rsphenamines as such, and the influence of these factors in the onset of dermat itis. At times the continued absorption of bacterial protein from focus of infection or sudden liberation of such proteins following flare-up in the focus (now well-recognized effect in allergic phenomena) due to arsphenamine (Milian) may be influential. Our own studies led us to suspect acute intercurrent infection as in the infectious asthmas, for example, to have marked sensitizing effect. This was particularly observable in several patients with tuberculous nodes. Milian among European uthors represents the group believing that infection, particularly of focal character is vital influence in the induction of cutaneous arsphenamine reactions. The obser vations of Lees on 86,000 injections, and those of Cathcart and Stokes and Kulchar and Stokes and Smith (1938) constitut the principal publications on the contributory influence of infection. The arsenical concepts include the suggestions of Moore and Keidel as to the vasculotoxic effect of the drug in both the skin and bone marrow The observations of E. Hoffmann, Spiethoff and of Milbradt on hepatic injury and the value of glucose and insulin and liver extract in treatment (p. 369); and the evidence of Osborne as to the accumulation of arsenic about the cutaneous capillaries and the disappearance of the drug coincidently with improvement in the dermatitis are recent contributions. Upon the basic fact of hypersensitiveness for which evidence may be found, for example in Fig 88, showing the small amounts of arsphenamine received by patients sustaining dermatitic reaction, may be superposed variety of other influences including impaired liver function from arsenic as such, which interferes with the proper metabolism of the drug as just mentioned, and impaired liver function from chronic or acute infection; subthreshold allergic shock in intolerant patients, nd the like. Damage to the suprarenals is suggested by the striking evidence of vasomotor imbalance and vasoparesis in patients with cutaneous arsphenamine reactions of the urticarial and dermatitic types. The intense itching accompanying them as suggested by Harris particularly as sign of deficiency of epinephrine and the vasodilation thus induced permits the development of the syndrome of Auer which, by permitting an increased supply of the allergen or irritant to the sensitive cells creates tissue explosion with exfoliative dermatitis in the skin nd inflammatory changes in other tissues. The role of arsenic as such, important though it unquestionably is, can hardly be regarded as indispensable or even t times as of major importance in exfoliative dermatitis as complication of the treatment of syphilis French, for example, from large experience recommends the practice of resuming the administration of the same brand and type of arsphenamine as soon as the patient is able to be up and around the ard again, his exfoliation just completed, and have seen personally examples in which this, t us highly dangerous procedure, has been carried through ithout serious results. Milian was ble to continue the administration of the same drug for number of injections after the onset of cutaneous reaction, the successive flare-ups disappearing ith the later and larger doses, situation quit inexplicable if arsenic as such and its accumulation and retention are the sole factors in dermatitic reaction (see Eighth or Ninth Day Erythema, p. 410). Here, in the field of the cutaneous toxicology of the arsphenamines, as in other aspects of the behavior of the human body under antisyphilitic treatment, complex of causes rather than any single causal element is probably operating The more recent experimental ork on arsphenamine llergy is considered on page 255

Hepatic Injuries.—Those induced by the arsphenamines are fortunately very rare at least in their acute manifestations and a good deal of confusion exists in their differentiation. The clinical aspects of this problem are discussed in Chapter IX on the control of reactions, and Chapter XVIII on the differential diagnosis of jaundice in syphilis. Hepatitis in the course of arsphenamine treatment, for this is a better term than arsphenamine hepatitis, has,

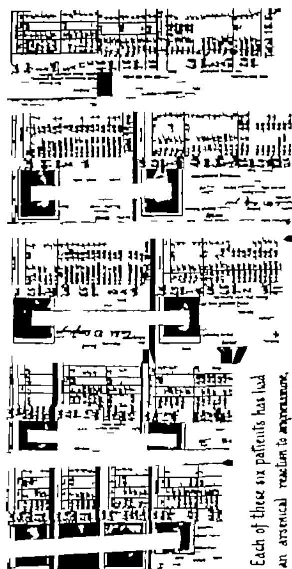


Fig. 88.—Chart hastily constructed for necropsy demonstration from clinical records, taken at random, of 6 patients who had had exfoliative reaction, including tw severe and one fatal; and 6 patients he had had really intensive treatment. All the intensively treated patients were receiving coincidently ith arsphenamine from 4 t 6 weekly injections of mercury succinimide usually 0.25 grain (0.01 Gm.) each. Most of them received coincidently sodium iodide intravenously from 2 to 20 Gm. daily None of the intensively treated patients reacted. T of the 6 who reacted had received practically no mercury

like dermatitis in all probability a complex of causes at its back. The commonly recognized forms are (1) the acute early type coming on within a few days or even hours after the injection of an arsphenamine derivative, whether the first or a subsequent injection in a series (2) the late or delayed type and (3) the acute yellow atrophy postarsphenamine. The course of the acute early type is usually benign without constitutional symptoms and terminates in

recovery though Stewart Vining and Bibby reported the case of a patient who, after an asymptomatic interval of several months following jaundice died abruptly of acute yellow atrophy of the liver The late arsphenamine jaundice is much the more serious of the two chronological types and may come on during a course of treatment, or some months or weeks after its completion The majority of these cases recover in six weeks to three months but in those with more severe onset, acute yellow atrophy is to be feared There is often enlargement of the liver but by no means necessarily Anorexia, nausea, weight loss, profound anxiety and nervous depression with the usual symptomatic concomitants of jaundice and a prodrome often of intense arthralgic symptoms are well recognized. Acute yellow atrophy may terminate either early or late cases, or appear with fulminating abruptness from a clear sky usually some weeks or months after the completion of a course of treat ment, in this respect resembling chloroform injuries to the liver Fever vomiting, chills, delirium excitement followed by coma and death may supervene in the course of an apparently benign jaundice

The various causal possibilities involved when jaundice and acute yellow atrophy appear in association with syphilis and the administration of arsphenamine include: (1) Syphilitic infection as the sole cause; (2) form of therapeutic shock due to previously existing hepatic syphilis flared up by the arsphenamine (3) rest interval relapse in the liver with the development of jaundice and other symptoms as hepatorecurrence (Milian); (4) a latent bacterial or virus infection, stimulated as result of the injection of the arsphenamine or engrafted on liver previously damaged by the drug (5) arsphenamine acting on liver previously damaged by syphilis (6) arsphenamine damaging the liver as such; (7) other disease processes which may produce jaundice.

The differential considerations involved in extricating the various items from the complex of jaundice in association with syphilis is summarized in the chapter on syphilis of the liver (Chapter XVIII, p 873)

In general it may be said that the jumble of toxic, infectious, syphilitic and surgically treatable factors in the picture of jaundice occurring in the syphilitic patient is responsible for confusion in the literature which swamps the inexperienced reader at once. Arsphenamine toxic icterus is the older and more familiar entity and having received extensive study in the early days of salvarsan it gets special emphasis in German writings. The French are divided between the Milian group who call for more arsphenamine for every case of jaundice because they interpret it as hepatorecurrence and the observers who contend that late icterus is product of arsphenamine poisoning resembling chloroform poisoning. These latter feel that damage to the liver can be demonstrated by various tests and that arsphenamine should not be used. British observers have been divided between those inclined to ascribe the entire process to arsphenamine, such as Stratby Smith and Hanson and Anwyl-Davies (1942), and other observers who have directed attention to epidemic features, notably the Cherryhinton military hospital epidemic in 1917 reported by the Salvarsan Committee of the Medical Research Council (1922) and series of cases observed by McDonald in 1918. Anwyl-Davies (1946) even contends that arsenoxide, "Mapharside," gives the lowest jaundice rate of the various arsenicals. In the United States the usual explanation of jaundice in patient under treatment with arsphenamine has been *post hoc, ergo propter hoc*. On the other hand, more attention has been given to the complicating factor of epidemic jaundice. Symmers called attention to new severe type of epidemic jaundice occurring in New York in 1920 with high mortality from acute yellow atrophy and not associated with syphilis or heavy-metal poisoning. Working with Brunsting and Lemon, Stokes pointed out that there had been an extraordinary increase in the incidence of jaundice among the patients of the Section on Dermatology at the Mayo Clinic in the years, 1919–20 which was not attributable to any change in methods of treatment. It was shown that this type of jaundice had distinctive prodrome suggesting an infectious element that it ran typical course that there was more than suggestion of epidemic background; that the process was hemolytic in character, as shown by the appearance of urobilin and urobilinogen in the duodenal contents, with restoration to normal on recovery and that it was possible in many cases to continue treatment with neoarsphenamine

throughout the course of such jaundice without the slightest ill effects from the arsenical treatment. It was, moreover, shown that the jaundice occurred in patients who had never had syphilis or treatment for it, that it followed treatment with mercury and iodide as well as with arsphenamine, and that it occurred in severe and typical forms, patients even dying from acute yellow atrophy who had not been treated for syphilis for as long as two years, whose Wassermann reactions were negative, who were free from clinical signs of activity or who never had had syphilis. A study by Blumer of the incidence of epidemic infectious jaundice in the United States clearly demonstrated the existence of an epidemic prevalence of the disease although its etiology remains obscure. A survey of cases in New York eliminated Weil' disease. Personal communications received at that time from observers on Long Island indicated that the disease may assume grave forms and be confused with surgical conditions of the gallbladder. Such cases were also observed in the Mayo Clinic and on exploration the preoperative diagnosis could not be substantiated, only diffuse hepatitis being found. Bodin published figures similar to those of Stokes *et al.* and since the publication of their conclusions, epidemics have been observed in other syphilis clinics of this country without any explanation traceable to medication or technic as such. The normal incidence of jaundice on a treatment service cannot, of course, be precisely estimated but should not exceed 1 to 1.5 per cent. Bodin incidence rose t 7 per cent. The Mekowski statistics referred to later give the incidence of jaundice as once in each 2000 injections of arsphenamine (0.80 per cent) and once in 8000 injections of neoarsphenamine. The incidence of jaundice in Stokes series by cases was 1.5 per cent of which incidence 91 per cent fell within the third and fourth of period of four years and was coincident with epidemic influenza throughout the United States. Wile and Sams (1934) reviewing the experience of the University of Michigan clinic found much evidence supportive of the conception of contributory infectious factor. Rugs epidemiologic study (1934) in the German navy is confirmatory. The recent literature on this subject has been reviewed by Stokes and Beerman (1941).

The mechanism involved in this peculiar association of epidemic infectious jaundice with the treatment of syphilis is still unsettled. Numerous writers have suggested that though arsenic may be predisposing factor the agent actually causing the jaundice and acute yellow atrophy is an organism from some intercurrent infection (virus) (Lancet, 1944). In this connection the ork of Opie should be recalled as demonstrating that in chloroform injuries to the liver much more marked and serious effects can be secured by the combination of chloroform administration and the injection of living bacteria than with chloroform alone. Hurst and Hurst have obtained similar results with manganese chloride and Bacillus coli injections. In Stokes studies of the duodenal flora of these cases no convincing results were obtained bacteriologically but there was definite evidence of duodenitis, hemolytic organisms were recovered by McDonald in the Newcastle epidemic and by Fraenkel but the results are subject to the usual criticism of bacteriological examinations made after death. Rugs incriminated the typhoid-colon group.

Hanger and Gutman (1940) have presented careful study of twelve cases of postarsphenamine jaundice in which icterus was not hepatogenous but appeared to be due to obstruction of the intrahepatic biliary tract. The clinical and pathologic features of these cases suggest distinct type of reaction to intravenous arsenicals.

Liver Function Under Arsphenamine Therapy.—The use of liver functional tests for the detection of arsphenamine damage to the liver has yielded conflicting results. Kolmer and Lucke found that even therapeutic doses of arsphenamine produced slight structural changes in the liver.

Widal, Abrami, and Iancovesco, using the hemoclasic reaction of Widal (leukopenia following the ingestion of glass of milk on the empty stomach) found evidence of hepatic insufficiency without jaundice or other overt signs eighteen and twenty four days after the end of normal course of arsphenamine treatment. Spence and Brett, using levulose test, thought they detected evidence of damage. MacKenzie Wallis believed he detected evidence of late damage rather than early. Kartamischew believed the action to be cumulative. American investigators have been less convinced that significant damage occurs. Chargin and Orgel, using the Meulengracht method for bilirubin in the blood serum, found that 17 per cent of 84 patients developed hyperbilirubinemia during arsphenamine treatment, the quantity increasing with successive injections of the drug. Schamberg and Brown applied the van den Bergh test and found no definite relationship to the amount of arsphenamine used, though they believed the test useful as guide to the resumption of treatment in patients who had been jaundiced. Greenbaum and Brown, using the Rosenthal modification of the phenoltetrachlorphthalein test (Rosenfeld-Schneider technic), found that no appreciable injury was done to the liver by considerable series of injections of the

arsphenamines. They concluded that the test ought to be performed in all syphilitic patients showing some form of intolerance to the arsenobenzenes (itching, tingling in the extremities, and mild dermatitis in particular). Icterus is too late a sign of toxicity in their opinion. Observations on the icterus index are summarized in Chapter XVIII. Irgang (1937) showed that while present day tests of liver function are of great value in detecting mild and severe grades of inflammation, they are incapable of disclosing incipient pathologic change. They are furthermore of somewhat limited value in differentiation of the various factors involved in the causation of jaundice during antisyphilitic therapy.

Personally, we believe it is very difficult to escape even the relatively weak evidence of an association between arsphenamine therapy and jaundice. It may well be recalled that Warthin gave it as an item of his autopsy experience in the arsphenamine era that hepatitis had become a common feature of practically all syphilitic patients with a history of intensive arsphenamine therapy. While it seems to us that this relation to arsenotherapy must be accepted, intercurrent infection is an important exciting cause in jaundice as it is seen at the present day in conjunction with the treatment of syphilis. The true arsenical cases are in general of the more fulminating type associated with other direct evidence of arsenical intoxication, including especially peripheral neuritis and exfoliative dermatitis, and are relatively rarely of the milder type.

Renal Injury.—This complication of the use of the arsenicals may be asserted to occur, for all practical purposes, only as the result of the administration of toxic doses or preparations. Mapharsen is stated by Levin and Keddie (1942) to be not especially nephrotoxic although two deaths due to kidney damage were attributed to its use in various reports. The urinary evidence of renal irritation occurred in one patient out of each sixty-four in their series.

While several examples were reported in the early years of the arsphenamine era (Nasta, Tucker), so that arsphenamine anuria is well recognized, its occurrence has been noted almost exclusively with the accidental administration of unneutralized or otherwise toxic solutions of "606. Its appearance as a complication automatically raises the question as to the correctness of the technic. "Extended investigations by Rappleye, Elliott and Todd, Bailey and McKay, Anderson, Weiss and Corson, Rabiro and Brown, upon the renal functional disturbances produced in man and animals by therapeutic doses of the arsphenamines using both renal functional tests and blood chemical determinations have shown that the injurious effects are practically nil. Single large toxic doses and presumably also moderate doses administered to definitely idiosyncratic individuals are, of course, another matter." Lemierre, Etienne, Bernard and Lambling have reported a case of anuria following neoarsphenamine (novarsenobillon) marked by severe pain over the kidneys and a thirty-six hour anuria. This pain over the kidneys Stokes observed in 5 successive severe intoxications with a defective brand of "606" and once with neoarsphenamine followed by albuminuria and cylindruria. In the case cited by Lemierre *et al.*, the nephrosis was hemorrhagic in character. The extraordinary tolerance of the kidney for arsphenamine is nowhere better illustrated than in the treatment of acute syphilitic nephritis in which a urine which boils solid and presents innumerable casts will clear almost immediately upon the administration of minimal initial doses of "606" or neoarsphenamine. In general in animal experimental work, at least, neoarsphenamine is, however, the more irritant preparation for the kidney. McFarland found the opposite, however, to be the case in man. Stokes has observed from time to time on the service at the Mayo Clinic the appearance of a reducing substance, in some cases undoubtedly glucose, in the urine following arsphenamine injection and absent in the interim. The patients were not subthreshold diabetics. One in particular was an elderly arteriosclerotic and another a young girl with prenatal syphilis. Whether or not the glycosuria was renal was not determined at the time. This complication is evidently rare.

Injury to the Suprarenals.—The evidence that arsphenamines seriously affects the suprarenals in the ordinary treatment of syphilis is at best tenuous. The mere good effect of injected adrenalin upon the nitritoid crisis certainly can hardly be accepted as proof.

Kolmer was unable to confirm Hirano on a deficiency of adrenalin in the blood after injections of arsphenamine. Osborne was unable to find any conspicuous concentration of arsenic in the

suprarenal cortex and believed that such evidence of injury as there is, is preponderantly vascular. In one patient Stokes had the opportunity to treat with an addisonian syndrome of the classic type apparently of syphilitic origin, the injurious effect of arsphenamine on the suprarenals was very apparent with each injection. A marked increase of pigmentation, diarrhea and profound *prostration with marked drop in blood pressure persisted for several days after each injection* but could be controlled by large doses of adrenalin per rectum and hypodermically. On giving up the use of arsphenamine and substituting mercury bichloride intravenously and later bismuth intramuscularly no ill effects were observed. At autopsy subsequently extensive damage to the suprarenals, presumably by the disease, was recognized.

Respiratory Injuries.—These follow the intravascular agglutination caused by acid arsphenamine "606" and also by the disodium salt. They also express themselves in the pulmonary edema phase of the nitritoid crisis and in the tendency to develop bronchopneumonia in the presence of acute respiratory infection when "606" is administered.

In such circumstances, and in fact, even in the absence of obvious respiratory infection, the administration of concentrated arsphenamine solution and acid arsphenamine is very apt to eventuate in bronchopneumonia, as in the cases reported by Schwerdtfeger and Tinker. De Beyrouth and Klauder have reported asthmatic wheezes associated with the intravenous injection of neoarsphenamine and with the handling of the drug in powder form, Klauder's case being in a physician who also developed a local sensitization dermatitis. Szarvas (1931) and also Saunders (1942) have reported arsenical asthma.

Arthritic reactions with swollen and painful joints occasionally occur in association with postarsphenamine febrile reactions and erythema multiforme. They are probably either the results of a flare-up in a focus of infection for which the arsphenamines have been blamed by Milian, or resemble the arthritoid manifestations accompanying certain urticarias and angioneurotic edema.

Injuries to the Blood and Hematopoietic System.—This group of arsenical by-effects now known to occur with every drug now used in the treatment of syphilis, including mapharsen, while not numerically large, is critically important because of the unpredictability, suddenness and highly fatal character of the reaction. Simple hemolysis of red blood cells apparently depends more on solvent concentration than on the drug and in modern procedures with special solvents and appropriate dilutions, is no longer of practical importance. Intravascular agglutination in a nitritoid crisis is also without clinical importance. The serious reactions to the arsenical drugs are classifiable under the broad category of conditioned toxic injuries, ably discussed by Fitz Hugh (1938) as the result of a wide variety of insults to the bone marrow produced by infections, drugs, allergens, cyclic factors in women, the fatigue state, perverted metabolism and deficiency states. The relative importance of arsenic and the benzol ring in these reactions to the arsphenamines remains undecided, but clinical experience clearly shows that the process of sulfonation in the manufacture of arsphenamine produces compounds such as sulfarsphenamine which have a markedly higher incidence of bone marrow injury than do the other types of arsenical. Stokes's experience with a patient suffering from aplastic anemia and repeated attacks of thrombocytopenic purpura who was nonetheless able to tolerate without difficulty the intravenous use of sulfarsphenamine, indicates the highly specific character of the injurious effect. The very minute amounts of the offending drug capable of producing it have been demonstrated by Epstein and Falconer and they showed furthermore that successive reactions lead to increasing sensitiveness to the drug, so that repetition of treatment after evidence of thrombocytopenia has developed is definitely and indeed exceedingly dangerous. Caletti (1940) and Brunet, Shaw and Reinhardt (1941) showed that the concurrent administration of an arsenical and other drugs such as the sulfonamides which can produce hematopoietic reaction did not increase the intrinsic risk from either alone.

Classifications of the types of bone marrow injury range from McCarthy and Wilson's four subdivisions of thrombocytopenia thrombocytopenia and granulocytopenia agranulocytosis and agranulocytopenia, and aplastic anemia to Burke's simplification into two types including thrombocytopenia and granulocytopenia. Actual cases are probably much more frequent than the reported incidence suggests, many being lost under such headings as purpura, agranulocytic angina, aplastic anemia, leukemoid reaction and arsenic poisoning. Burke's estimate based on the experience of the Whitechapel Clinic, approximates 0 4 per cent of treated patients, but the fact remains inescapable that a large clinic may operate for years without the occurrence of a single case. Aside from the factor of drug selection there are probably conditioning elements, as Fitz Hugh indicates, including intercurrent infections, pregnancy and so forth, which abruptly step up the incidence under special circumstances and at special times The destruction of blood platelets is the primary clinical and pathologic fact, and upon it ensue the purpuric hemorrhages which are often the earliest clinical signs. Dodd and Wilkinson pointed out, however as have other authors, that in cases tending to the granulocytopenic type of reaction with the development of aplastic anemia, thrombocytopenia may not appear early or even at all and the patient go on to profound destruction of the bone marrow with or without regeneration and the development of a fatal aplastic anemia which would only be recognized by blood studies for which at first there would be little symptomatic indication. Moore and Foley especially emphasized that stomatitis and dermatitis, quite as much as purpura, should be the signal for an immediate blood study and the appearance of immature cells should be a warning to discontinue arsenical treatment or to proceed with the greatest caution. The relative immunity of childhood and of the young, healthy specially favorably conditioned adult represented by the personnel of the United States Navy to aplastic anemic complications following the use of the most hematopoietotropic drug sulfarsphenamine is yet to be explained. Possibly relative freedom from focal and serious conditioning infections, adequate diet and vitamin intake, and similar as yet unevaluated influences are important. Vitamin C, however which has been employed in large doses by Epstein and Falconer was without effect after the thrombocytopenic reaction had developed

A drop in red blood cell count may precede, accompany or follow the fall in leukocytes and may reach astonishing figures before death supervenes. The lowest reported leukocyte count in the Dodd and Wilkinson series is 136 the lowest recorded red blood cell count 80,000, and the lowest hemoglobin, 13 per cent. The lowest platelet count, reported by Gorke, was 10,000. The purpuric hemorrhages and the necroses which develop about the teeth, gums and tongue and which lead to confusion with agranulocytic angina of the idiopathic type are of course, secondary manifestations due to the activity presumably of mouth flora and "opportunistic bacteria (Fitz-Hugh) unleashed by the drop in leukocytic defense. An abrupt onset of pneumonia following stomatitis may be the first warning of the gravity of the patient condition if blood-counts have not been previously taken

Allergic Reactions to the Arsenicals.—The study of allergic reactions to the arsenicals has made rapid and in some particulars paradoxical and puzzling progress during the past several years True tissue hypersusceptibility is thus far definitely known only for the respiratory tract and the skin. It seems possible that the intestinal mucosa may react in this way in certain otherwise unexplainable examples of intolerance.

By far the most important aspect of hypersusceptibility and allergy in

ordinary treatment work is cutaneous sensitivity to the arsenicals. This fascinating subject still in process of experimental and clinical development, gives some promise of yielding a safe procedure for determining whether or not a patient who has once shown a dermatitic reaction to an arsenical can continue this form of treatment. The following is a brief résumé of present knowledge.

It seems probable from the investigations of Jadassohn and Bloch that urticarial and eczematous reactions in the skin must be sharply distinguished from the standpoint of the allergies involved. The eczematous manifestations are particularly examples of intrinsic cutaneous rather than vascular sensitivity and it is these which are of the more importance in dealing with the arsphenamines. Bloch succeeded in showing in his experimental work on the toxin of primrose that direct introduction of powerful sensitization-inducing substance into the skin was capable of sensitizing even normal persons. Klauder one of the first American students of the subject showed in 1920 that there was disconcerting intimacy of connection between exfoliative dermatitic reactions in patients and the previous occurrence of intradermal injection of an arsphenamine through technical error resulting in tissue leakage around an improperly entered vein. Klauder observations have since been confirmed, especially by Nathan and Munk, and by Frei, who have also recognized flare-up reactions at the sit of intradermally injected arsphenamine when patients subsequently received intravenous injections of the same drug. Moore *et al.* Shaffer (1934) Stokes (1934) Cormia (1941), E. Epstein (1937) and others on the other hand, could not notice ny conspicuous association between instances of arsphenamine leakage and subsequent onset of dermatitis. The observations just cited, together with those of other observers, have, however led t definit tendency t discourage the ttempt to test for arsphenamine sensitivity by any procedure hich outright breaks the surface of the skin and introduces the drug to the deeper epithelium. Unaware, of course, of these observations, which followed them by a number of years, Klauder had employed scratch test and Stewart and Maynard had employed intradermal injections of dilut rsphenamine solutions in the effort t determine whether or not patients ere sensitive cutaneously to the arsphenamines. Frei (1928) produced skin sensitivity t neoarsphenamine (Hoechst) in guinea pigs by angle intracutaneous injection. No anaphylactic shock was observed in these animals after intracardiac reinjection. Attempts to sensitize other animals such as dogs and rabbits gave negative results. Sulzberger (1929–1930) stated that the sensitivity to neoarsphenamine (Hoechst) can be induced and demonstrated only in the skin and that the skin sensitization could be inhibited if an intracardial injection was given twenty-four hours after the intracutaneous preparation, but desensitization could not be induced by an intracardial injection hen given after the hypersensitivity had developed. Sulzberger and Mayer (1931) in animal experimental studies, conducted at the Jadassohn clinic in Breslau and later in New York, obtained in their earlier ork what appeared to be definite evidence of sensitization of guinea-pigs by intradermal injection of arsphenamine. T their surprise, however these results did not prove susceptible of satisfactory repetition under different physical conditions and geographical location, so that the whole subject was to some extent throw into confusion. One of the factors responsible for these differences was the diet of the animals in that green fodder inhibited and dry fodder favored sensitization. Sulzberger and Oser (1934) observed for the first time that the amount of vitamin C in the diet had some definite influence on sensitization, large doses having an inhibitory effect. I 1934 Sulzberger and Simon found differences in the incidence nd degree of sensitivity in New York as contrasted with Boston. They in conjunction with Williamson and Morrell, showed that the degree of hypersensitiveness depend also upon the brand of the neoarsphenamine employed since certain lots of arsenicals have high sensitization index. They demonstrated that guinea pigs are in general specifically sensitive to the arsenobenzol complex and not to other trivalent or pentavalent organic and inorganic arsenicals although subsequent reactivity to pentavalent arsenicals may develop as rare example of polyvalent sensitivity (Epstein, 1937 Golz, 1939; Franks and Fisher 1940) Cormia (1941) pointed out that the more complex trivalent arsenicals are much likelier to cause dermatitis, while arsenoxide is incapable of producing sensitization in animals since it has low sensitization index. Frei (1937) orking on guinea-pig sucklings, studied the question of why infants do not acquire neoarsphenamine exanthemata. Animals one week old showed absolute resistance to sensitization. This resistance gradually disappeared as the animals grew older. The findings of Frei and Sulzberger have been confirmed by numerous investigators (Kaplan and Moreinis, 1930 Kapuściński, 1930 Ma, 1938 Sézary *et al.*, 1933; Streitman and Wiedmann, 1937 Chapman and Morrell, 1935 Cormia, 1936, 1937.) Mayer (1931), Kallós and Kallós-Deffner (1933) and Cormia obtained different results on studies on the allergic nature of arsphenamine dermatitis utilizing the Schultz-Dale test on the isolated guinea-pig uterus. Cormia, for example, obtained completely negative

results. The relationship of intercurrent infection and dietary factors in arsenical sensitization is fully discussed on pages 369 and 372. Landsteiner and Jacobs (1936) obtained, after intracutaneous injection of dilute unneutralized arsphenamine solution, a high degree of skin hypersensitiveness in practically all injected animals. When such sensitized animals were given neutralized arsphenamine 606 solution intravenously a considerable percentage died in typical anaphylactic shock. This shock occurred more regularly and was more severe when the solution was mixed with guinea-pig serum. These experiments definitely indicate that arsphenamine, a simple chemical, nonprotein, is capable both of producing skin hypersensitivity and of producing anaphylaxis and anaphylactic shock. This method also gives regular and definite results. Frei and Sulzberger (1936) using this method found that arsphenamine 606 regularly produces cutaneous sensitivity to itself as well as to two brands of neoarsphenamine. Intracutaneous injection of arsphenamine 606 generally produced anaphylactic sensitivity to arsphenamine 606 but not to the neoarsphenamines. Frei (1941 1942) showed that guinea-pigs sensitized to arsphenamine did not exhibit increased susceptibility to sensitization to other drugs (quinine hydrochloride, acetyl salicylic acid, barbital). He found that the skin sensitiveness of sensitized guinea-pigs was directed against aromatic arsenicals in general and not against arsenic nor exclusively against arsphenamine. An effort was made by Fuhs and Riehl to demonstrate the passive transference of arsphenamine sensitivity to normal persons, the methods employed including intradermal injection of blood serum from a hypersensitive patient (Prausnitz-Küstner method); intradermal injection of vesicle fluid, and so forth. Ensbruner has apparently accomplished passive transfer with blood serum. The successful induction of passive transference in some of these cases has been questioned by Schoch as being due probably to transference of minute quantities of arsphenamine to the skins of the normal subjects, rather than to any actual transfer of sensitivity. In any event, these methods, together with the percutaneous or intradermal introduction of arsphenamines into the skin by hypodermic needle or scarification are at present deprecated as probably dangerous and likely to induce sensitivity if not already present.

Much hope was placed in the method of patch testing devised by Jadassohn and employed in this country recently by Chargin, Sulzberger and Crowley and by Schoch. Robinson (1936), Jordan and Osborne (1933), and Beerman (1936). In a considerable series of tests performed at the University of Pennsylvania Clinic Schoch, for example, succeeded in showing that the arsphenamine factor in induced sensitivity to a double salt such as bismuth arsphenamine sulphonate could be detected by the patch test and that the test be of very considerable value, though not absolutely infallible in the detection of significant degrees of cutaneous sensitivity and risk of arsphenamine dermatitis (Jordan and Osborne, 1933 Beerman, 1936; Bechet, 1939). Routine patch testing may induce sensitivity in some persons. Beerman has apparently observed such a case on our service (1933).

From an extended study of the arsenical patch test, we, as well as Robinson, have concluded that the patch test is not specific enough to be implicitly relied upon as an advance indicator of arsenical sensitization since a patient with a negative patch test may develop arsenical dermatitis on further administration of arsenicals and vice versa. It has failed as a reliable means of detecting the specific allergic factor in a cutaneous reaction other than typical arsenical dermatitis occurring during arsenical treatment. It may not be entirely harmless. Because, in the hands of experts it may serve as a guide to further treatment, especially with arsenoxide (Schoch 1940) we are detailing the technic of this test.

The technic of carrying out the patch test and the method of reading and interpreting the results, may be summarized as follows (Schoch). 0.3 Gm. of neoarsphenamine is dissolved in 1 cc of distilled water. Bismuth arsphenamine sulphonate solution of the same concentration may be used as the test solution where this drug is suspected. Mapharsen patch tests are performed with 3.3 per cent solution. A small linen patch is saturated with this test solution, applied to the intact skin of the arm and covered in turn with tracing cloth, bound down at the margins to form an airtight chamber by adhesive tape. At the end of twenty-four hours the patch is removed and the first reading made. A strongly positive reaction consists of an acute dermatitis at the test site, with vesiculation, as shown in Fig. 99. Partial positive reactions that show only erythema and a few papules are not regarded as evidence of definitely established cutaneous hypersensitiveness to the arsphenamines, only pronounced dermatitic reactions being regarded as clearly positive. After the inspection of the patch site twenty-four hours after application, the impervious dressing is removed and the test site reinspected about one-half hour later at the end of which time strongly positive reactions sometimes develop on exposure to air. The test site should be reinspected forty-eight hours and even a week after the impervious dressing is removed to recognize the last trace of a delayed positiveness. The test site of a strongly positive reaction usually returns to normal in about three weeks. Strongly positive patch tests with neoarsphenamine are interpreted as showing too high a degree of cutaneous hypersensitiveness to permit

further arsphenamine therapy Negative patch tests, on the other hand, were assumed by Schoch to permit cautious attempts to continue arsphenamine therapy usually with some other form of this group of drugs tha that previously employed

In conjunction with this work, Schoch performed series of experiments indicating a practical haza d in arsphenamine work and coincidently the extremely minute amounts of the arsphenamines which are capable of inducing sharp dermatitic sensitivity reactions in susceptible patients.

Using the Lloyd and Lloyd modification of the Abelin test, he showed that even on syringes used for the intramuscular injection of an arsphenamine after they had been rinsed and boiled in ter for adequat sterilization, there still remained sufficient traces of arsphenamine, extremely minute though they must have been, to induce sensitization reactions in patients previously known to be sensitive to the arsphenamines. Thu a bismuth suspension given in syringe previously used for bismuth arsphenamine sulphonate and cleansed only by rinsing and sterilization is capable of inducing an exfoliative dermatitis due to arsphenamine in patient previously sensitive to the arsphenamine group of drugs. It is necessary to clean syringes used in such work with soap, water and cotton swabs, t insure the protection of sensitive patients.

Fig 89—A positive patch test with neoarsphenam ne, in patient sensitive to the drug The erythematous plaque is studded with vesicles.

While variety of theoretical considerations, including the extreme difficulty of interpreting intradermal test procedures involving necrosis-inducing substances and colloids, are involved in the earlier test method and have brought them into discredit both on the score of trustworthiness and safety it seems very probable that considerable measure of reliance, though not unqualified, may be placed on the result of the patch test as above described i deciding upon the fitness of patients for further arsphenamine therapy once dermat tic reaction has occurred It should be stated, however that conservative observers, Klauder for example, have expressed themselves as strongly opposed t any attempt t continue any arsphenamine therapy whatever in patient who has once shown a severe dermatitic reaction in treatment for syphilis. Certainly in many aspects of the disease this stand is *absolutely justified and the only period in which we feel any* inclination to continue the use of arsphenamines if patch test results permit is in the treatment of early syphilis, where the issue of infectiousness and radical cure is involved as at no other stage *of the disease.* I such cases cautious trial of arsenoxide (mapharsen) may be considered as possible saf procedure (Schoch 1940)

Procedure after Patch Tests.—The degree of specificity involved in the arsphenamine sensitization reactions is undoubtedly considerable but not invariably absolute Thus, Cole found that two third of his patient ho had had arsenical complication could continue arsenical

treatment cautiously and of those who had had two complications, 28 per cent could continue arsenical treatment. Moore *et al.* showed that the allergic state of the hay fever subject materially influenced the severity of his reactions to intracutaneous test, thus suggesting that this factor may materially affect the onset of arsenical cutaneous sensitivity. Following negative patch tests in patients who have been suspected of cutaneous hypersensitivity or about 3 months after recovery from dermatitis, no larger dose than 5 mg. of the least reaction-producing drug available (sulpharsphenamine, arsphenamine "606," neoarsphenamine, bismuth arsphenamine sulphonate and mapharsen produce cutaneous reactivity in about the order named) should be employed in resuming treatment in a given case. At the first sign of intolerance arsenical treatment should be permanently stopped (intravenous testing, Robinson, 1936).

Sulzberger's protection of animals by intracardiac injection following cutaneous sensitization by an arsphenamine has led to the suggestion that in any case in which leakage occurs about a vein during an arsphenamine injection, a determined effort should be made to complete the intravenous injection in order to protect the patient against the development of sensitiveness. Mayer has reported the onset of the eruption in exfoliative dermatitis at the site of arsphenamine leakage around a vein. The precise applicability of this conception to man, in view of its uncertainties in animals, is undetermined, but it furnishes a useful practical maxim for the treatment room: If leakage occurs, withdraw the needle but attempt to complete the injection by entering some other vein. At the present time there is no known method of cutaneous desensitization to the arsphenamines applicable to man.

Idiosyncratic Reaction to the Arsenicals.—If the term idiosyncrasy be accepted in a broad sense as including toxic and injurious responses to the improperly metabolized drug even though we are as yet unfamiliar with the steps involved in the various processes, idiosyncrasy to the arsenicals exists but is fortunately comparatively rare. In this group should be included encephalitis hemorrhagica, for example, which is a totally unpredictable accident, fulminating acute yellow atrophy definitely traceable to the arsenicals alone, explosions of exfoliative dermatitis following the first or the first two or three injections of an arsenical despite reasonable precaution and proper dosage, hemorrhagic disease and aplastic anemia associated with special susceptibility of the bone marrow or the endothelium of blood vessels, both structures known to be markedly susceptible to arsenical injury in certain cases. Emphatic protest, however, should be registered against the all too prevalent disposition to blame accidents and complications following the administration of the arsenicals upon a hypothetical idiosyncrasy upon the part of the patient. Technical error and unfamiliarity with modern knowledge of the proper use of the arsenicals form the basis of a large proportion of pseudo-idiosyncrasies. The technical means of avoiding reaction are discussed in Chapter IX, but it is obvious from what has been said thus far that the correct technical preparation of the drug for injection, a proper rate of injection in intravenous medication and proper preliminary attention to the patient in the matter of examination and appraisal, are the chief preventives of alleged idiosyncratic reaction.

Certain constitutional states are recognized as predisposing toward idiosyncratic responses. Among these should be included profound constitutional disturbances involving infections and intoxications, conditions involving severe grades of vascular injury such as alcohol and lead poisoning and diabetes, skin hypersensitivity, pregnancy and the thymicolymphatic state. Serious disease of or injury to the liver as the principal metabolizing station in the administration of the arsenicals also contributes definitely to idiosyncrasy. Figure 90 itemizes in more detail "the seven bads" and outlines the background against which reduced tolerance, expressing itself in pseudo-idiosyncrasy, is projected. A large proportion of idiosyncratic accidents strike

the central nervous system and the skin In the former case they are most frequently assigned by the puzzled and disturbed medical attendant to the

Fig. 90.

REDUCED TOLERANCE TO THE ARSENICALS—"THE SEVEN BADS"

1 Bad brains and cords—acut meningeal and diffuse encephalitic processes, serious vascular involvement, myelitis.
2. Bad livers—early acut diffuse hepatitis, extensive late hepatitis and cirrhosis.
3. Bad spleens—cirrhotic splenomegalies.
4 Bad vascular systems—myocarditis, coronary lesions, conduction lesions, aneurysms, markedly febrile subacut bacterial endocarditis.
5 Bad lungs—advanced tuberculous nd septic processes, especially if febrile. Acut bronchitis.
6. Bad kidneys—chronic nephroses and lat interstitial nephritis.
7 Bad skins—eczema, especially seborrheic history of cutaneous hypersensitiveness, personal or familial, previous dermatitis, urticaria (chronic).

A Contraindication May be Relativ Not Absolute, and Controllable by Skilful Management.

category of Herxheimer reactions or therapeutic shock with which, of course they may easily be confused, for the distinction between a focal or diffuse

Fig. 91

A SCHEMATIC SUMMARY OF THE ARSENICALS IN CLINICAL PRACTICE

Arsphenamine Proper ("606")

Advantages.	Disadvantages.
The standard of comparison. Generally acknowledged therapeutic superiority	Cross mortality higher than neoarsphenamine
Lowest incidence of relapse, especiall neurorelapse in early syphilis, if used ith mercury or bismuth.	Dermatitis higher than neoarsphenamine but less than silver and sulpharsphenamine.
Most marked effect on blood Wassermann.	J undice more frequent than with neoarsphenamine.
Most rapid response ith fewest injections	Minor reaction higher than with low doses of neoarsphenamine, but only slightly higher ith therapeuticall equivalent doses.
Prolonged effect.	Technicall more difficult slow and cumbersome
No more immediat reactions than eaker preparations, if used in therapeutic equivalence	Hemolytic
Stability under market conditions.	Agglutinates red blood-cells in large doses (disodium salt)
Comparative st bility of solutions.	Hard on the lungs.
Uniform toxicit	Harder on the liver than neoarsphenamine.
Dependable nd uniform in therapeutic effect.	More irritant t veins. Less desirable in one-vein patients, infants, t
Better tolerated by the kidney than neoarsphenamine.	

Herxheimer reaction in the brain and a true encephalitic reaction to the drug is sometimes drawn with the greatest difficulty The presence of anything suggesting an appropriate background for idiosyncratic reaction calls for the

very greatest conservatism in initial dosage which should be not more than one fourth or one third the normal for the adult by weight. A drug should moreover be selected which is least injurious to the group of structures most involved in accordance with the principles set forth in Figs. 91-94

Therapeutic Shock and the Arsenicals.—While perhaps not properly regarded as a toxic manifestation of the use of the arsenicals therapeutic shock and the so-called "Herxheimer flare-up" are so general and in fact so almost a physiologic part of the pharmacological action of this group of drugs that a physical description is in order at this point.

The Herxheimer reaction under the administration of the arsenicals is best illustrated by a series of figures. It has a focal and a systemic phase but so far as is known no local reaction occurs at the site of injection such as is observed

Fig 94.

A SCHEMATIC SUMMARY OF THE ARSENICALS IN CLINICAL PRACTICE

Neoarsphenamine

Advantages.	Disadvantages.
Specially high-grade lots almost equal arsphenamine. Average is second best.	More relapses. Low therapeutic efficiency in the doses often used.
Very low mortality in doses up to 0.6 gm	As many complications as arsphenamine when used in therapeutic equivalence.
Dermatitis rare in low doses.	More apt to produce injury to the blood and blood-forming organs and cerebral vessels than arsphenamine (aleukemia, encephalopathy)
Jaundice rare in low doses,	Less effect on Wassermann than arsphenamine
Less toxic for liver than arsphenamine	More irritant to kidney than arsphenamine.
Non-hemolytic	Unstable in solution.
No pulmonary by-effects.	Slight errors in technic markedly increase toxicity (shaking, standing).
Marked tonic effects.	Marked deterioration possible under market conditions (also tropics)
Best tolerated by the weak, debilitated, cachectic very young, and very old patient.	Therapeutic efficiency variable and may often be low and even nil without warning to user
Safest to begin with if in doubt as to tolerance	Larger number and more frequent injections required.
Less irritant to tissues and veins	
Suited to ambulatory technic.	
Convenient to give little apparatus, small amount of solvent.	

in the use of tuberculin, whose relation to the immunology of tuberculosis bears no resemblance to that of arsphenamine in syphilis. The focal phase of therapeutic shock reaction under arsphenamine is well illustrated in the extra genital chancre in Fig 95 and consists of increased swelling redness and discharge where such was originally present. Note that the satellite bubo as well as the chancre is involved All other syphilitic lesions in the patient's body are similarly affected. The reaction develops within eight to twelve hours after intravenous injection upon an acute syphilitic process in an easily penetrable tissue and then rapidly subsides It is seldom repeated with a second injection. In fact, if it is repeated, it suggests underdosage and inefficient drug or a resistant strain of organism Stokes has seen three definite Herxheimer reactions following three neoarsphenamine injections in a secondary eruption

which cleared very slowly In processes which are difficult of access (i. e tissues of low vascularity or those which like the nervous system are relatively impenetrable to the arsphenamines) the local Herxheimer reaction is delayed and may not reach its height for days or even several weeks after the treatment is begun An example of the delayed Herxheimer in osseous syphilis showing clearly the increased swelling and discharge is given in Fig 96 Objective evidence of the occurrence of the therapeutic shock reaction in the meninges,

Fig. 95.

A SCHEMATIC SUMMARY OF THE ARSENICALS IN CLINICAL PRACTICE

Sulpharsphenamin

Advantages.	Disadvantages.
Therapeutically between neo- and arsphenamine. At least equal t neoarsphenamine.	Clinical status not fully established.
Suited t intramuscular use	Higher incidence of dermatitis.
High penetration of the nervous system.	Tendency to serious injury to vascular system as in aleukemia hemorrhagica.
Action on resistant blood Wassermann and neurosyphilis, by intramuscular root *better than neoarsphenamine*	Effects less lasting than arsphenamine(?)
	Larger number and more frequent injections.
Avoidance of Herxheimer effects t some extent by slower bsorption.	Question whether it should be used at all in adults because of reactive qualities.
Very stable under market conditions.	
Solution very stable.	
Low animal toxicity	
Few immediat reactions.	
Technic of administration as simple as neo- or simpler (intramuscular)	

Silver Derivatives

A new angle of ttack on resistant cases.	Higher incidence of dermatitis.
Efficiency higher than other drugs in proportion t arsenic content, but mid y between arsphenamine and neoarsphenamine in dosage used.	Possibility of argyria.
Apparently less vascular disturbance in serious organic lesions.	Higher incidence of immediate minor reactions.
	Less effect on Wassermann than either neoarsphenamine or arsphenamine
	Question if mercury or bismuth should be used simultaneously
	Little know of selective or special action.
	Dose must be small t void trouble.
	Technically d fficult (saline necessary dark solution)
	More expensive tha arsphenamine

delayed as might be expected by the impermeability of the tissues, is seen in Fig. 97 in which the rise in cell count s an index to meningeal reaction shows a definite curve upward through a period of days before its final reduction to normal

The importance of the focal phase of the arsenical Herxheimer reaction is proportional to the location and physiologic importance of the tissue in which it arises. This fundamental principle deserves and has received repeated emphasis in the foregoing discussion

A Herxheimer reaction i the tibia is seldom significant A Herxheimer reaction in the larynx, here the tissue per se is not likely t suffer serious damage by the flare-up is, however of vital importance because the edema may close partly cicatricized passage completely with result ing asphyxiation if help is not at hand. A Herxheimer reaction in the wall of an aneurysm, due

Fig. 91

A SCHEMATIC SUMMARY OF THE ARSENICALS IN CLINICAL PRACTICE

Mapharsen (Arsenoxid)

Advantages.	Disadvantages.
Pure crystalline form soluble in neutral, acid, or alkaline solutions.	Not sed long enough t determine per manence of results.
Practically complet freedom from produc ing nitritoid reactions.	Best effect require t or more injections per eek.
Greater therapeutic effect ith smaller doses of arsenic	May produce kidney or gastro-intestinal irrit tion,
Oxidation (aeration) does not increase toxicity	Inferior t neoarsphenamine in treatment of syphilis in pregnancy
May be injected rapidly	Pain along shoulder relatively frequent.
Intramuscular injection possible	Chemotherapeutic index nee 1(?)
Lowest cutaneous toxicity and general re action incidence of any trivalent arsenical.	
Adaptable t foreshortened treatment schemes.	
May be used, with caution, in patients not tolerant of the arsphenamines.	
Less disagreeable taste	

to the unintelligent use of an arsphenamine, may weaken the wall enough t cause rupture following the first or second injection (Fig. 713), and in the liver may result in a sudden portal obstruction with increased ascites that may be serious (Figs. 676, 677)

A B

Fig 85 —The effect of therapeutic shock (Herxheimer) upon a chancre of the lip. A shows the lesion on the upper lip before and B show it t elve hours after the first intravenous injection of 0.3 Gm. arsphenamine Note the local edema of the lip, the ccentuation of the lesion itself the enlargement of the satellite bubo below the left ramus

The ystemic phase of the therapeutic shock following arsenicals is rarely serious unles the grossest overdosage has occurred It may create a temporary impression that the patient is gett ng worse It is usually accompanied by

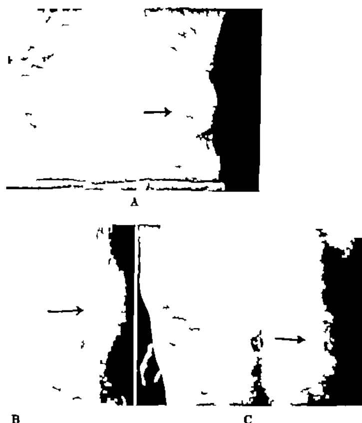

Fig 96 —Three stages in the course of gumma of the ribs under treatment showing the delayed Herxheimer reaction in bone gumma. A, The swelling before treatment was begun. B, Great increase in swelling and discharge produced by the first three arsphenamine injections (Herxheimer reaction) C, End-result after four months. Complete healing. A surgical exploration at the height of the Herxheimer reaction had failed to disclose any signs of tuberculosis or malignancy (See case history Fig 617)

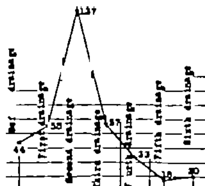

Fig 97 —Lymphocytes in spinal fluid of patient at the outset of treatment showing Herxheimer like curve

fever (Fig 98) if the spirochetes are abundant or the process active The chart here shown is characteristic of the reaction in early syphilis. Systemic response usually occurs with the first injection and in the days when sharp distinctions

were drawn between cases eligible for the so-called "abortive cure" and those in which the infection was regarded as general, considerable prognostic significance was attached to it. If the patient was serologically negative on the blood when his primary lesion was first diagnosed and treatment begun, the occurrence of fever in the twenty four hours after the first arsenical injection was regarded as indicating that his infection was general and abortive cure impossible. It is now, of course, entirely clear from the immunological consideration discussed in previous chapters that no such method of estimating the status or progress of an early syphilitic infection is justifiable. It often happens that in the primary stage a patient who, on examination, shows no signs of a secondary eruption will on the day following his first arsphenamine injection be found to have a definite roseola. To the extent that this constitutes objective confirmation of the syphilitic character of the previous manifestations it has value in diagnosis but its value is not so great that it is ever permissible to give an injection of an arsenical to a patient with an undiagnosed genital lesion suspected of being a chancre in the hope that he may develop a sec-

Fig. 98.—The febrile reaction in therapeutic shock (Herxheimer) following the first injection of arsphenamine (0.3 Gm.). The height of reaction was reached eight hours after injection (disregard upper numerals). This patient had a primary lesion on the index finger with a positive blood Wassermann reaction and positive darkfield, but no signs of secondary eruption. Note that no fever followed any subsequent injection.

ondary eruption as a diagnostically confirmatory Herxheimer or therapeutic shock phenomenon.

It is not infrequently observed that patients serologically negative on the blood on the day preceding the first injection of an arsenical become seropositive from twenty-four to seventy-two hours later. While this need not necessarily be labeled a Herxheimer effect, it is clinically important as indicating that the patient properly belongs in the treatment classification of seropositive primary syphilis as distinguished from the prognostically more hopeful seronegative primary syphilis. This will be reemphasized under the treatment of early syphilis.

On the other hand in late syphilitic lesions the therapeutic shock reaction may have at times definite diagnostic value and it is well worth while to include observation for focal reaction following a single moderate dose of arsphenamine among the diagnostic criteria in therapeutic test. No provocative test with an arsenical should therefore ever be given to a patient with an observable lesion without making arrangements to see the patient on the two

days following the injection to detect any focal flare-up and without watching the temperature during the twenty-four hours following the provocative injection While the therapeutic shock often fails to reach visible proportions, when it does, it is a considerable aid in piecing together the evidence in a doubtful case If the initial arsenical dosage be made large enough, therapeutic shock reactions of any grade of severity may occur Not a few of the terrific reactions with high fever great prostration and subsequent alleged idiosyncratic reactivity to the arsenicals were observed in the early days of intravenous arsphenamine treatment, and are still seen at the hands of the inexperienced who employ maximum adult doses of 0 6 and 0.9 Gm. of neoarsphenamine for example, for the initial injection. Such high dosage brings out the worst effects of therapeutic shock with no advantage to the patient, with definite disadvantage from injury to his physiologic reacting power when low dosage would have kept the flare-up within safe limits.

Symptomatic Therapeutic Shock.—This term applies to an increased severity of symptoms as distinguished from visible signs. Following the use of the arsenicals it is limited practically to the late manifestations of the disease especially in the cardiovascular and nervous systems, and rarely complicates either diagnosis or treatment in the early stages of the infection where symptomatic favorable response is usually almost immediate.

Nonspecificity of Arsenical Therapeutic Shock.—The Herxheimer flare-up following the arsphenamines is not an absolutely specific reaction and has been observed following the administration of the arsphenamines in tuberculous subjects with both focal and local processes It also occurs in other spirochetoses susceptible of treatment with the arsphenamines and Stokes personally noted it in sodoku or rat-bite fever

Arsenic Resistance (Arsenic-fastness) —This has already been sufficiently discussed under the general consideration of drug-fastness in syphilis, of which arsphenamine resistance is the most familiar example (p. 146)

Ocular Lesions Produced by Arsphenamines.—The rôle of the arsphenamines in the production of ocular lesions has been discussed in the masterful study by Zimmermann. Subsequent reports have merely added examples to Zimmermann s classification. These injuries fall into three classes (1) True toxic reactions, as conjunctival hyperemia, transient myopia, retinal hemorrhages chorioretinitis, corneal necrosis and keratitis associated with exfoliative dermatitis (Kirby 1930 Hyde 1931 Chan 1912) (2) Ocular therapeutic shock or Jarisch-Herxheimer reaction with serious consequences following in an extensively diseased eye All types of uveitis and choroid involvement may be aggravated. Interstitial keratitis is rarely aggravated while the danger in optic neuritis and tabetic optic atrophy of a Herxheimer reaction may be serious Ophthalmoplegias rarely occur as a therapeutic shock reaction (3) Neurorecurrences or iridorecurrences. Ocular lesions following insufficient treatment of early syphilis as part of a neurorecurrence (oculomotor) or as an iridorecurrence With increased knowledge of treatment these reactions have been reduced almost to nil although Skirball and Thurmon (1935) report that 2.7 per cent (20 cases) of their patients with early syphilis developed severe ocular reaction from trivalent arsenical. We recall no such complication among *our patients The prevention of these lesions depends on intensive prolonged* and systematic treatment of early syphilis.

Rate of Action of the Arsenicals.—To those who are familiar in memory with the leisurely involution of active syphilitic lesion under the treatment

of mercury and iodide days the term "arsphenamine miracle is no exaggeration (Fig. 90) Syphilids requiring months for involution disappeared in weeks and few weeks, at that. The physiologic involution of the chancre which ranged, according to the size of the lesion, from three weeks to three months excluding the disappearance of induration, was reduced by the arsphenamines to a matter of one to three weeks. A late syphilid covering the entire thigh of a woman healed completely in five weeks. Figure 90 graphically presents the really astounding effect of an active arsphenamine on destructive late lesions The rate of healing of lesions is to some extent a check upon the efficiency of an arsphenamine product and for that reason it is well worth while for the practicing physician to watch the involution of chancre and secondaries and if the average primary has not healed over in three weeks, or papular secondaries disappeared leaving only pigmentary traces, by the fourth or fifth injection, he can afford to question his dosage scale or the efficiency of his drug. On the other hand, with the increasing tendency to use the arsphenamines synchronously with bismuth such a test becomes much less significant.

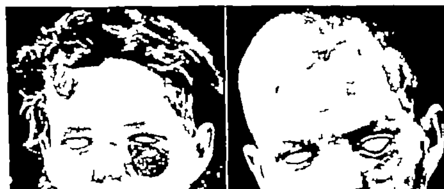

Fig. 90—An illustration of the rapidity of action of arsphenamine. Healing of two large rupial ulcers by tw injections of 0.5 and 0.4 Gm. at eekly intervals The photograph was taken on the fourteenth day before the third injection

The arsphenamine miracle extends to the symptomatology as well as the signs, and the disappearance of severe osteocopic and periosteal pain, cephalalgia, and other acute symptoms within twenty four hours after a therapeutic dose of "606" or even "914" had become a commonplace

The therapeutic miracle of the arsenicals, welcome as it is to physician and patient, is a not wholly unmixed good. The immediate recession of the disease into invisibility produced in this way leads too often to underestimation of its seriousness by the physician, shortening of the empirical maximum which experience has now shown to be essential for "cure" and desertion of the treatment regimen by the patient just at the time when it should be receiving his most assiduous and devoted cooperative attention. It will interest students of the arsphenamines to know that the American Cooperative Clinical Group studies in early syphilis showed clearly that under standard systems of treatment the largest part of the reversal of blood serological tests in primary and secondary syphilis (Chapter XIV) is dependent on the arsphenamines and in fact is carried through by the arsphenamines largely unaided by heavy metal It is for this reason among many others, that continuous treatment with the

arsphenamines to and beyond serological negativity without any interruption by rest intervals now appears as such a vital consideration in the management of early syphilis.

ARSENICAL THERAPEUTIC PRINCIPLES

Methods of Administration.—Arsphenamine has been administered by practically every method except fumigation and inhalation by mouth, per rectum, by subcutaneous injection by intramuscular injection by intravenous injection, intraspinally and intracranially

Of these, administration by mouth was shown by Schamberg and his coworkers to be ineffective though the drug can be given in a capsule with reducing agent such as sodium sulphite Arsphenamine per rectum has been more fully studied Suppositories were for time used in the treatment of infants and persons with inaccessible veins, but in the doses thus employed the drug was practically ineffective and is now completely discarded in favor of the intramuscular use of bismuth and the intramuscular arsphenamine preparations such as sulpharsphenamine and bismarsen. Mehrtens found that five times the intravenous dose (4 Gm.) of neoarsphenamine could be administered by rectal tube high in the sigmoid with the securing of a concentration of the drug in the blood stream considerably higher than that obtainable by intravenous injection. No effort seems to have been made, however to exploit the method or test its ultimate value

Arsphenamine Subcutaneously and Intramuscularly—Ehrlich in 1910 placed intramuscular injection foremost among the methods of administering arsphenamine ("606") from the standpoint of theoretical effectiveness. The necrosis due to the alkalinity of the suspension and the intrinsic tissue-destroy ing effect of the arsenical drug however put a stop to the effort at practical adoption.

So severe were the destructive effects of earlier injections that Takahashi found from three hundred t four hundred days to be required for the restitution of the tissue t an injection site to the stat of quiescent scar If softening and evacuation occurred, the abscess, while sterile contained large part of the injected drug, which was thus lost in the discharge. At the present day the sites of old intramuscular injections of original "606, often calcified to stony hardness are objects of curiosity to the syphilologist

In spite of this initial setback, there has been consistent effort throughout the arsphenamine era t return to intramuscular methods hich deserve t least theoretical commendation. Craig and Harrison have shown that the effect of the intramuscular use of arsphenamine on the Wassermann reaction is definitely superior to that of intravenous injection. Behn and Stokes felt that much of the superiority of sulpharsphenamine, such as it was, depended upon the use of the intramuscular route. The possibility of securing essentially equivalent therapeutic effects by drugs of relatively lower arsenical content, such as bismuth arsphenamine sulphonate when given t short intervals intramuscularly is certainly suggested by our experience with this drug The question as t whether any of the present-day arsenicals have reached an optimum from the standpoint of their usability in intramuscular procedure is, however serious one and far from answered. The demonstration that technic of administration has good deal to do with making intramuscular use even of severely irritant drug, practicable has been convincingly supplied by the work of Harrison, Whit and Mills of the British Army and of Richard Sutton, Fordyce and Rosen in this country It cannot be forgotten, however that ork of this sort has been carried through under army disciplinary restraints or t the exercise of force of personality and professional prestige which the verage pract tioner and even the majority of clinics can hardly expect to bring t bear Reaction and pain produced by methods of treatment, as must be repeatedly reiterated, are grave bar to the success of modern treatment technics and these objections have been far from met by ny preparation now on the market.

Intravenous Arsphenamine Administration.— As the overwhelmingly popular technic of today this forms the background of practically all the treatment principles discussed in the literature and in this book The rates of absorption

of neoarsphenamine and sulpharsphenamine given intramuscularly however are quite similar to those for the intravenous route so that they are to some extent translatable into common terms The technic of these procedures is fully discussed in Chapter VIII

Intra-arterial arsphenamine therapy has been studied in animals by Kritschewski and Winogradowa (1932)

The Intraspinal Administration of the Arsenicals.—In the first edition of this work, the intraspinal administration of arsphenaminized serum and the discussion of its usefulness occupied approximately twelve pages. The change of syphilological front has relegated the method to a position of relatively *minor importance replaced by tryparsamide* and fever therapy though still useful in certain symptoms and complications of tabes dorsalis especially Kierland and O Leary (1941) however believe this attitude toward intra spinal therapy is unjustifiable. The following brief summary here given will assist those who desire to use this method

From the outset two groups of procedures have developed that of Swift and Ellis, who, in 1912, administered serum of arsphenamine-treated neurosyphilitic patients into the spinal canal with favorable results; and that of Ravaut, who in 1913 reported on the direct injection of dilute neoarsphenamine solution int the spinal canal. Later, drainage of spinal fluid to carry the circulating arsphenamine in the blood through the choroid plexus was carried out by Gilpin and Early and endorsed by Dercum. The procedure of Swift and Ellis modified by Ogilvie who "reinforced" the blood serum introduced into the spinal canal by minute amounts of neoarsphenamine, has survived to the present day Modifications of the Ravaut technic in spite of initial difficulties have been developed and endorsed by Wile and Gennerich. The Swift Ellis method, which is the only one that ill now be discussed in this work, had its inception in the observations of Taege Meirowsky and Hartmann, Plaut, Gibbs and Calthrop, and others to the effect that the serum of syphilitic patients has curative properties. Swift and Ellis at first employed the serum some time after the injection of arsphenamine, but inasmuch as the test became negative on the blood serum within two hours after intravenous injection, they were later led to draw the blood within an hour after injection and to inject the diluted, inactivated serum into the spinal canal the following day Such serum has since been spoken of as auto-arsphenaminized because the patient receives intraspinally only such arsphenamine and arsphenamine colloidal combinations as are in circulation in his own blood stream after intravenous injection. Kolmer has in his use of the method emphasized the importance of the time after injection when the blood is drawn. When it is recalled that 60 per cent of the arsphenamine is fixed outside the blood when the injection is just completed, and that at the end of an hour only 10 per cent remains in the circulation, the importance of this consideration is evident. At best, the amount in 15 to 30 cc. of serum obtained at the end of t enty to forty minutes cannot be large. The addition of amounts such as ⅟₁₀ to ½ mg of neoarsphenamine per dose, as practiced by Ogilvie, was therefore rational procedure On the other hand, it was contended by the opponents of intraspinal therapy that the amount added is *not equal to that which can be found in the fluid after massive intravenous* injection. Swift and Ellis, however ascribed considerable effect to the influence of antibodies in the serum and it has been contended that normal nonarsphenaminized serum does not appear to give these same results. Looking back on the matter in the light of our growing understanding of the mechanism of antisyphilitic treatment, it seems very probable that all the intraspinal procedures, including the use of mercury (Byrnes), are essentially that of protein irritant to increase meningeal permeability Whatever may be the mode of action, there is no question in our minds that the buffering of any added drugs by the serum is an essential safety factor in the procedure and that even under the best conditions and with reasonably large experience and trained staff we have never felt the hazards of the Ravaut and Gennerich methods of direct introduction of the arsphenamines into the spinal fluid t be small enough in American practice to justify their continued use

Mechanical factors play part in intraspinal medication and give evidence from the character of the reactions that maximum therapeutic effect is obtained near the point of entry of the injection. This has led both to the introduction of arsphenaminized serum into the ventricles by Hammond and Sharpe, and Solomon, and its use in intracisternal injection after the technic of Ayer Gennerich ingeniously carried the neoarsphenaminized spinal fluid upward from the site of lumbar puncture by running in below it spinal fluid obtained from second simultaneous punc

ture two vertebrae below the first. There can be no question that such method raises the field of action materially higher toward the base of the brain, and the procedure has merit as part of the treatment of primary optic trophy and basilar conditions for which it can be employed.

It cannot be too vigorously emphasized that adequate technical facilities and personnel, knowledge of the principles of the treatment of syphilis as well as an intraspinal technic, and a large bump of caution are essential to the saf employment of such a procedure as the Swift Ellis or other forms of intraspinal therapy The safety range of the method is small and every detail in technic drug, and medical judgment is vital T one who has seen the increase from ½ to ⅓ mg. reinforcement in the practice of confrère seemingly cause 3 successive cases of saddle anesthesia in patients who had previously without difficulty tolerated series of ½ mg. treatments, the safety factor becomes very impressive. T one who has been ppealed to for emergency advice in aid of patient dying of arsenical myelitis after a practitioner had forcibly with syringe, injected fully 2 or 3 cc. of concentrated solution of neoarsphenamine into the spinal canal, the dangers of popularization of difficult technical procedure become pparent. Such small matters, even with the technic t its best, as drop in speed of the centrifuge, by failing to throw out all the red blood cells, may on single occasion make all the difference between crop of reactions and an uneventful day There is no doubt that the general practitioner should not attempt intraspinal measures. Those specialists who are equipped to do so should be exceedingly chary of tentative and experimental variations on the established technic.

With due regard to the physical status of the patient and his tolerance of the arsenicals, Klerland and O'Leary (1941) feel that intraspinal (Swift Ellis) therapy is indicated in patients with asymptomatic and meningeal neurosyphilis early tabes dorsalis, and early neurosyphilis not responsive to a trial of routine treatment. It is of value as postmalarial therapy in neurosyphilis without mental changes, and in certain cases of syphilitic cardiovascular disease with complicating neurosyphilis Moore and his associates have considered intraspinal therapy as second best for optic atrophy

Progress in the Technic of Arsphenamine Administration.—Certain basic essentials involving the solvent, the asepsis, the rate of administration and in the case of arsphenamine 606" itself the technic of neutralization have gradually come to the front as *sine qua non* to an adequate intravenous technic.

Reactions Due to Water—The earlier intravenous injections were followed by reactions, usually febrile in character which, according to the national persuasion of the observer were attributed to the solvent by the Germans and to the drug by the French.

The introduction of commercial methods of issuing solvent with drug in the form of properly prepared ampuled water has now so simplified the situation for the users of neoarsphenamine and mapharsen and the intramuscular modifications that to all intents and purposes only the user of "606" meets the problem in its original significance and proportion.

The Tubing Reaction.—Gum rubber tubing used in the gravity method of administering arsphenamine may contain toxic substances of unknown composition apparently associated with an excess of sulphur compound in connection with the vulcanizing process, as show by analyses performed through the courtesy of the B F Goodrich Co. after Busman and Stokes had published their observations on the reaction The toxic substance is dissolved from the bore of the tube by slightly alkaline solutions and can ultimately be sufficiently dissolved way so that used tubing causes after time to give rise to reactions. The reactions thus come in crops and are severe enough to be thoroughly alarming and t times even conceivably f tal They are described in connection with the prevention of reaction in Chapter IX. Typical toxic responses can be produced in dogs by the use of new rubber tubing of toxic brand in the adm nistration of dilut sodium hydroxide solution intravenously or even of citrated blood. The reaction can be entirely prevented, as indicated in the *Public Health Service technic, by soaking all rubber tubing over night in normal sodium hydroxide solution*, being careful that all parts of the lumen of the tube are reached.

Concentrated Solutions of th Arsphenamines.—Undoubtedly large part of the striking lead held by neoarsphenamine over the original "606" is to be attributed t simplification of

the technic of intravenous injection of the former drug which as reported by Ravaut in 1912. He showed that neoarsphenamine could be administered without injurious effects in concentration of 1 cc. of properly prepared distilled water per decigram. This concentration permitted the use of the syringe in place of the more cumbersome gravity apparatus, did away with the increased possibility of reaction incident on the injection of large amounts of hypotonic solution and perhaps improperl prepared solvent, and permitted the use of small needles with less discomfort to the patient and less damage to the vein. An enormous saving of time was at first realized by rapid injection, double-edged advantage, as was later discovered when the time factor in reactions began to be ppreciated.

The concentration of sulpharsphenamine and bismuth arsphenamine sulphonate for intramuscular injection is substantially higher than for intravenous use and 1 to 2 cc. of solvent represents the maximum amount advised In fact, the higher concentrations seem to be better tolerated than the lower ones.

Acid Arsphenamine (606) Solution.—Efforts t produce vest pocket technic for the administration of original arsphenamine (606) have not been so successful. Neutralization and dilution, with gravity administration is thus far absolutely unescapable with this drug. All efforts to do way with the neutralization of arsphenamine, with or without the original dilution requirements (40 t 50 cc. solvent per decigram) can be regarded now as obsolete Schamberg, Raiziss and Kolmer showed acid arsphenamine solution t be 50 or 60 per cent more toxic than the alkaline disodium salt. The concentration of alkaline arsphenamine solutions has likewise been attempted and in place of the original Ehrlich specifications of 50 cc. per decigram and the present Public Health standard of 25 cc. per decigram, arsphenamine (606) was given by Brayton and Nelken in concentrations of 10 to 20 cc. of solvent for the entire 4 and 6 dg. doses. Cannon (1920) revival of the syringe technic for arsphenamine injection has not thus far been widely used. W have had personal experience with all modifications of this type of procedure, using water as solvent, and can unhesitatingly condemn it as giving rise t disconcerting proportion of reactions on the table, prostration, vomiting, pain in the back, sweating and weakness, even if no pneumonias ensue Injury to veins is common. It is possible that thorough study of buffers, including gelatin, might yield results that would lead to the popularization of concentrated solution technic for "606.

Use of Buffers and Chemically Modified Solvents.—A number of efforts have been made to modify the toxicity of the arsphenamines by the use of special vehicles, including blood serum, glucose solution, gelatin solutions, calcium chloride, sodium cosinate, sodium thiosulphate vitamin C and its derivatives. Physiologic salt solution is, of course, the simplest modification of solvent possible and where quantities larger than 100 cc. are to be given there is apparently some reduction in toxicity probably due to the influence on hemolytic effect and on the irritation of veins leading to spasm and thrombophlebitis.

Adrenalin can also be added t arsphenamine solutions though for its physiologic effect rather than for any chemical modification of the diluent This plan, tried at the Mayo Clinic, by Osborne (unpublished) proved helpful and deserves further study It occasionally makes possible the treatment of patients who would be otherwise obliged to discontinue treatment because of nitritoid reactions but is only recommended in the case of the larger dilutions employed with arsphenamine.

The Rate of Administration.—This implies the rate of delivery of the drug to the blood stream rather than the rate of injection of solutions of varying concentration and in today practice is reducible to a simple rule of thumb — deliver arsphenamine solutions slowly and mapharsen fast. By Public Health Service standards, arsphenamine should be delivered at the rate of one decigram per minute (20 cc. of solution) and one decigram in thirty seconds for neoarsphenamine A reactionless office technic calls for even slower administration in markedly reactive patients, and it is only w th the greatest difficulty and the most determined attention to the matter that one can keep his tendency to speed up administration down to the limits of greatest safety The adoption of automatic controls, including needles so small when used with

a syringe technic that it is impossible to give a hurried injection, and burette clamps on the tubing of gravity apparatus are desirable Mapharsen in contrast to the arsphenamines should be so injected in the words of the manufacturers, that the time elapsing from the insertion of the needle until the syringe has been emptied and the needle removed from the vein should be no more than thirty seconds " The official five-day intravenous drip technic calls for an hourly dose of mapharsen of 0 02 Gm. in 200 cc. of 5 per cent dextrose solution The daily dose is 12 hourly doses or 0.24 Gm carried in 2000 to 2400 cc. of dextrose solution Leifer gives the rate as 3 cc. per minute

Temperature of Solvent.—Practically all drugs of the arsphenamine group are now dissolved in water at room temperature.

Local Anesthesia—Efforts have been made to overcome the discomforts of intramuscular injection of the arsphenamines by the use of local anesthetics, as in the case of bism th preparations. Two per cent novocain or butyn, tw t four drops in the solvent, may be employed and seem helpful

Dosage and Interval in Arsphenamine Administration.—*Before taking up* this topic it would perhaps be well to refer to Fig 100 which gives some dosage maxims applicable in general to syphilotherapy The effects, both therapeutic and toxic, produced by the arsphenamines are functions of a rather complex dosage technic which must be mastered if the best results are to be obtained The factors of greatest practical importance are discussed below

Arsenical *vs.* Therapeutic Equivalents.—The proper determination of the dose should be if possible on the basis of therapeutic effect as determined by the trypanocidal index. Using this method of determination Kolmer made the important observation that the therapeutically equivalent dose of neoarsphenamine as compared with arsphenamine is not one third greater but twice as great. Thus, if 0 6 Gm is the maximum therapeutic dose of arsphenamine 1.2 Gm will be the maximum therapeutic dose of neoarsphenamine one of course comes into collision with toxicity and in certain cases the conflict will be irreconcilable so that it will never be possible to secure the same therapeutic effect from one drug that can be secured from another On the other hand, it is possible by adjustment of intervals between injections to compensate to some extent for the effect of reduced dosage and in this simple statement lies the secret of much disappointment in the use of the less powerful arsenicals on dosage systems which, with respect to interval particularly are adapted only to the most powerful Thus, the interrelations between dose and interval have led to the development of what might be called "course" concepts in arsphenamine technic.

The Arsphenamine Course—Course concepts in the use of the arsphenamines unfortunately rest on a less satisfactory biochemical basis than do those outlined in Chapter VI for bismuth Part of this state of affairs depends on the greater difficulty of interpreting the metabolism storage and toxicity of arsenic as compared with bismuth. The results of intensive therapy which are still in process of evaluation, may entirely change our concept of courses and dosage of arsenic per kilogram necessary to produce "cure" (see Chapter V)

The Shift Toward Continuity of Administration.—Recent years have brought a definite shift toward continuity of treatment in the use of the arsenicals administered by standard treatment systems. It has become apparent that the safety margin of the drugs with properly adjusted dosage is large that

reactions are, to a considerable extent, due to technical error and misapplication that the close observance of every prescribed precaution makes possible the very great prolongation of treatment in time and that moderation in dosage still further increases tolerance without serious loss of therapeutic

Fig 100

A SUMMARY OF ARSENICAL THERAPEUTIC PRINCIPLES

1. Know the system applicable to the selected drug; never expect the best from one drug by the system adapted to another
2. Know the arsenical content and attempt to secure therapeutic equivalence by frequent smaller or less frequent larger doses.
3. Know the complications, administration technic and after-care peculiar to each drug. Here lies our worst weakness. Many complications are avoidable and preventable.
4. Treat *continuously not intermittently or irregularly in early syphilis.*
5. Treat intermittently or with alternations and rests in late syphilis.
6. For "606" use the weekly interval and 6 to 12 injection course
   For neoarsphenamine use three to five days early one week late and 10 injection courses.
   For sulpharsphenamine use one week and 8 to 10 injection courses.
   For mapharsen use three to five days in early syphilis, weekly in late syphilis, 10 injection courses. Foreshortened intensive systems described in Chapter XIV
   For bismuth arsphenamine sulphonate use three to seven days and 30 to 60 injection courses.
   For silver arsphenamine use five to seven days and 8 to 12 injection courses.
7. Dosage for women (unless pregnant) now tends to equal that for men, weight for weight.
8. Initial dosage is never more than half full dosage.
9. In arsphenamine "preparatory treatment" for avoiding therapeutic shock and paradox, initial dosage is nearer one tenth adult normal, very slowly increased
10. In early syphilis, less than half the adult full dose is subtherapeutic and favors relapse and failures.
11. In relying on an arsphenamine alone, give adult male 0 07 to 0.1 Gm. per 25 pounds body weight with "606" 0 1 to 0.15 Gm. with "914"; 0.01 Gm. with mapharsen; 0.05 to 0.07 Gm. with silver arsphenamine; 0.05 to 0 07 Gm. with sulpharsphenamine; 0.05 Gm. twice as often, with bismarsen. The curative total dose of mapharsen is currently rated at 1200–1800 mg (20–30 mg per kilo)
12. In giving heavy metal simultaneously reduce the maximum dosage given above one third, the minimum dose not at all.
13. Never begin with an arsphenamine on the above dosage scales if the patient
    (a) Is incompletely examined.
    (b) *Shows signs of serious localization of syphilis to vital structures, especially heart, liver nervous system, eye, or ear*
    (c) Is a "wreck" from other cause.
    (d) Is an untreated diabetic
    (e) Has active tuberculosis.
    (f) Is sharply febrile
    (g) Has an extensive unexplained dermatitis.
    (h) Is a high-grade nephritic
    (i) Has had trouble with the drug before
    (j) Is in danger of neurorecurrence (see early syphilis)
14. A system of treatment ending with an arsphenamine is left hanging in the air Bring it safely down to ground with a heavy metal tail.
15. Don't blame "idiosyncrasy" and reactivity automatically on drug or patient, and stop. If the situation is beyond you, seek advice without delay

effect. Probably the crucial demonstration was that of Moore and Kemp, and most recently of the American Cooperative Group, on the paramount worth of continuity as a general principle in the treatment of early syphilis This however cannot be literally applied to the use of the arsphenamines, which

were, in fact, employed intermittently in the systems of treatment involved in the work of these investigators. In a sense, continuity of treatment effect reaches its peak in the single massive dose systems now coming into use (see Chapter XIV)

Some astonishing records of tolerance, particularly for neoarsphenamine exist, several patients with neurosyphilis in our experience having received from their practitioners a hundred or more weekly injections without a break; and one report by Photinos apparently establishes a world record—that of a woman with prenatal syphilis who weighed only 39 to 45 Kg. (85 to 100 pounds) yet who tolerated without the slightest sign of reaction 230 injections of neoarsphenamine in an elapsed time of approximately three hundred and sixty weeks (1922 to 1929) 190 injections of the series being of the maximum dose of 0.9 Gm.

Whatever may be said of the merits of continuous treatment in early syphilis, the intermittent use of the arsphenamines is still distinctly the preferred technic for late syphilis, where resistance-building is often more important than direct action on *Spirochaeta pallida*

The Interval between Arsphenamine Courses.—In early syphilis this is determined in the continuous system of treatment by the heavy metal where it is used in alternation with the arsphenamines, or by a piece of empirical guesswork as to the rate at which accumulated arsenic from a prolonged course is likely to be eliminated. In general it may be said that intervals longer than six to eight weeks between courses of "606" even though filled by a heavy metal, represent the upper limit, and four weeks the lower limit in vigorous treatment, especially of early syphilis In the treatment of latent and late infections these intervals between arsphenamine courses are prolonged to ten or twelve weeks while the heavy metal is being administered, and may even be added to by an additional complete rest period from all treatment ranging from four to six weeks In general, the principle which should apply is essentially that of individualization and evaluation of the acuteness of the process A bonfire in the nervous system, if it is not at once subjected to tryparsamide or fever therapy should be subjected to prolonged continuous treatment as in an early infection. A relatively stationary process in a greatly debilitated individual demands periods of recovery from the therapeutic pounding for full utilization of the tonic effects of arsenical drugs.

Certain Tolerance Concepts.—Just as it is becoming evident that the arsphenamines may be used in longer courses than was at first believed advisable, so it has been shown though to what good purpose it is difficult to say that enormous doses of these drugs can be tolerated without serious degrees of reaction, provided the technic of administration is irreproachable.

Initial Dose, Age Weight and Sex Factors.—The principles governing *initial dosage* are summarized under items 7 8 and 11 of Fig 100 and are absolutely dependent on the absence of discoverable contraindications At no point in the treatment of syphilis at the present day could the profession better afford to sloganize individualization, for the damage done by the first injection of an arsphenamine is often serious and too often irreparable. Initial dosage should always be modified by a consideration of the patient's general condition, the special structures involved and the activity of the syphilitic process. Between the pitfall of subtherapeutic dosage and the dangers of therapeutic shock and paradox, the half-dose rule constitutes only a fair compromise and should not be routinely applied beyond the secondary stage of the disease or the period of latency

Weight factors, while the most obvious of all to the laboratory worker are often the hardest for the clinician to grasp One sees otherwise competent men administering identical doses to strapping policemen and scrawny girl clerks without a moment s reflection, evidently slaves to a dosage table While in the middle range of adult weights, 140 to 160 pounds the ordinary adult maximums apply for the effect which one desires to produce a weight-dosage ratio for each of the commonly used drugs in American practice is given under item 11 in Fig 100 Arsphenamine dosage for women formerly accepted at two thirds to three fourths that of men is now more and more nearly identical weight for weight. In old age it is more important to make a physical appraisal and be guided by the conditions found than by mere age. The dosage for early syphilis in elderly robust men may be reduced one fifth below that for the young adult. In infancy the dosage is usually given by age, but above 100 pounds weight an adult scale may be employed for neoarsphenamine or sulpharsphenamine, the dosage scale up to three years being

	Intramuscular Gm	Intravenous (jugular) Gm
Under two weeks.	0.05	0.03
Two to twelve weeks	0.1	0.03–0.1
Three to nine months.	0.15	0 1 –0.15
One to two years.	0.2	0.15–0.2
T to three years	0 25–0.3	0.2 –0 3

From three to eight years of age the dosage reaches 0.5 Gm. neoarsphenamine intravenously for therapeutic equivalence from eight to twelve years it is 0 6 Gm The initial intravenous dosage up to three years should not exceed 0 05 The dose of "606" at twelve years is 0.3 Gm that of bismuth arsphenamine sulphonate is 3.5 mg per pound or 7 mg per kilogram of body weight. A practical schedule based on age as employed by Chambers and Koetter is given in Fig 101 For children the initial dose of arsenoxide (mapharsen)

Fig 101

DOSAGE OF BISMARSEN IN CHILDHOOD

Age.	Dosage (dissolved in 2 cc. solvent)	
Tw weeks	10 t 20 mg	0.1 to 0.2 cc.
Two to six eeks	20 to 30 mg	0.2 to 0.3 cc
Six to twelve weeks	40 to 50 mg.	0.4 t 0.5 cc
Three to twelve months	75 mg.	0.75 cc.
	Dissolved in 1 cc. solvent	
One to tw years	100 mg	0.5 cc.
Two to three years	100 mg	0.5 cc.
Three to four years	100 t 150 mg	0.5 to 0.75 cc.
Four to five years	150 to 200 mg	0.75 to 1 cc
Five to fourteen years	200 mg	1 cc

From Chambers and Koetter Arch. Dermat. and Syph., 23 1065, 1932

should not exceed 0.0005 Gm (0.5 mg.) per kilogram of body weight the tota dose should average between 0 0005 and 0 001 Gm (between 0.5 and 1 mg) per kilogram of body weight.

Pregnancy demands, in our experience systematic reduction of dosage to about two thirds the adult normal by weight, to insure safety In febrile

conditions of nonsyphilitic origin it is wise not to exceed 0.1 Gm. neoarsphenamine for the first dose to test the tolerance. In diabetes and anemias, particularly of the primary type, the dosage for the first several injections should be one half to two thirds normal weight scale and if acidosis is present, the diabetic phase should be treated before arsphenamine is begun. Lesions of the second and eighth cranial nerve, early or late, call for great caution in dosage at the outset and preparatory treatment with a heavy metal is preferable. To avoid therapeutic paradox, if an arsphenamine system is selected, very slow increments of dosage, beginning with 25 mg. of neoarsphenamine or bismuth arsphenamine sulphonate at intervals of two to four days is the only safe approach.

Dosage and Interval in Nonspecific or Resistance-building Effects from Arsenical Treatment.—One half or two thirds the maximum dosage with weekly intervals and series of eight to ten injections the interval being extended toward the last and an interval of two to four months between arsphenamine courses is appropriate to the securing of this type of effect, discussed in greater detail on page 150.

THE TRIVALENT ARSENICALS INDIVIDUALLY

Comparisons of the Arsphenamines and Selection of Drug for Various Purposes.—While the practitioner is inclined to take a little too seriously the pharmaceutical fireworks that accompany on to the market each slight shift in the molecular formula, there is, especially in the last several years a distinct trend toward significant improvement in the trivalent arsenicals. It is unwise, however to expect radical and startling differences with each new modification, when at best the variation introduced may not affect 10 per cent of the patients on whom it is used in any distinctive fashion.

Estimation of the Value of an Arsphenamine.—The evaluation of the clinical worth of an arsphenamine is somewhat less difficult than that of heavy metal, but none the less is by no means easy. It cannot be accomplished by any one criterion. It is very apparent from the clinical course of syphilis in general that reversal of the serologic reaction as such does not appraise the ultimat influence of the drug upon the infection, for many infections retain full virulence and even infectivity and go on to disastrous complications under cover of negative blood serologic reaction. The healing of lesions is not holly trustworthy. The disappearance of spirochetes from lesions within varying periods of time is not proof of the ultimat curative power of the drug under investigation. Observation for relapse is too seldom part of clinical reports. The superiority of new preparation can be demonstrated to some extent by employing it upon cases in which the older preparations have failed. The fact that the new preparation may succeed because it offers another angle of attack on drug-fast organism and that it may be no more effective as routine treatment of many cases than the drug it supplants, must, of course, be borne in mind. The usefulness of an arsphenamine is dependent not alone upon its action on the disease but upon its reaction on the patient. Increased mortality and increased incidence of serious if not fatal complications, such as dermatitis, may make the use of even powerfully curative drug inadvisable. A notable example of this, in our opinion, is comparative newcomer the therapeutically effective sulpharsphenamine. On the other hand, systematic detoxification, as we have several times remarked, may be carried through t the expense of therapeutic effectiveness. Preparations which have been in clinical use for only three or four years cannot be regarded as completely out of the experimental stage and should be employed with the greatest circumspection by the inexperienced or the practicing profession t large. The therapeutic guides given are only tentative and may be reversed within comparatively short time by improvements in manufacture and technical administration as well as fuller study of clinical effects.

Arsphenamine Proper (606) from the Therapeutic Standpoint.—The onrushing revolution of massive dose and intensified systems with and without

fever therapy will, almost inevitably remove from the field of practice the landmark of arsphenamine "606" the basis of all comparison in the past twenty years the most widely used drug in the Cooperative Clinical Group the pet of specialists, and the one which most syphilologists familiar with the older systems would select, if they could for the treatment of their own infections were they so unfortunate as to acquire them. Accordingly all extended discussion of this drug in theory is here omitted and reference should be had to the *second edition of this work.*

Neoarsphenamine.—The enormous popularity of neoarsphenamine was due to ease of administration combined with a comparative freedom from immediate and disconcerting complications It is now rated as the most reaction-producing of the standard and generally used trivalent arsenicals, sulpharsphenamine perhaps excepted. It is much more variable than "606" with regard to therapeutic effectiveness and it has been clearly shown both by Dale and White and by Voegtlin and his associates that individual lots of the drug on the open market may be absolutely worthless therapeutically even though they may have passed the official toxicity tests and be to all appearances perfectly satisfactory *Much of this lack of uniformity has now been ironed out* (Probey 1939) Dale showed the relation of toxicity to solubility the more soluble being the less toxic drug

Raiziss, Elvove Freedman and others have shown that what is marketed as neoarsphenamine often contains sulpharsphenamine-like bodies in relatively high proportion and it appears from the work of these various investigators that there are at least two and possibly three quite distinct types of neoarsphenamine on the market. Similar observations were made by Fordyce Rosen and Myers and connected with the erratic reactivity of the drug as employed therapeutically The toxicity of neoarsphenamine, dose for dose, is 2.5 times less than that of arsphenamine (Raiziss) and its solutions are nonhemolytic (Kolmer and Yagle)

The basic disadvantages of the drug, which must be taken into account in routine therapeutic work, include its rapid oxidation and the enormous increase in toxicity which takes place on shaking or other forms of aeration of the solution. This increase may amount to a hundred times within a few moments, as Roth has shown. The reaction expectancy of neoarsphenamine increases with the age of the drug (Probey and Harrison, 1938) In addition these investigators (1939) reported that temperature, time of exposure and *moisture content of the powder affect the stability of neoarsphenamine the* deterioration varying directly with these factors. The drug must therefore be made up dose by dose, and handled with genuine delicacy and attention to detail. It is the mark of the greenhorn to squirt neoarsphenamine solutions, for example, from syringe to tumbler Once in a syringe free from air bubbles however its toxicity does not increase for several hours, as Kolmer Schamberg and Brown have shown. Much of the technical detail, quite as significant though less vexatious in time consumption than that involved in the use of "606" has not been appreciated by the average physician. In contrast to arsphenamine, neoarsphenamine should never be allowed to stand. If it does not dissolve almost instantly it should be thrown away and complaint made to the manufacturer In its therapeutic use, smaller doses, shorter intervals, and longer courses should be the rule and the once-a week standard of "606" administration laid aside. The drug lends itself particularly well to combined use with bismuth to the securing of tonic effects in debilitated patients and nonspecific effects on patients who do not have syphilis (p 151) In the latter case the longer intervals are however employed. Although 0.3 Gm. is accepted

as an initial dose for the average adult, it is on the borderline of questionable effectiveness especially in early syphilis, and should be promptly increased with the second or third injection. The distinct tendency to erratic behavior in neoarsphenamine makes it wiser to use smaller doses and shorter intervals than to risk the maximum doses of 0.9 Gm even with weekly intervals

Comparisons of Arsphenamine and Neoarsphenamine: Therapeutic Effectiveness.—Cannon and Karelitz, studying the action of the two drugs in infections of not more than six months duration when treatment was begun, with subsequent treatment and observation periods of not less than six months, found in 430 patients that arsphenamine was clinically the more effective drug As criteria they used the disappearance of visible lesions; the reversal of the Wassermann reaction complications arising from administration of the different drugs, and the number and nature of relapses. Heavy-metal treatment was in many cases used concurrently

The Cooperative Clinical Group found in its material dealing with this question, involving comparison of 2534 cases treated with arsphenamine (606) and 355 cases treated with neoarsphenamine (914) under the same conditions, that "606" in its various combinations with heavy metal therapy reverses the blood Wassermann reaction to negative within three months or less in 28.5 per cent as against 18.9 per cent under neoarsphenamine. This efficiency is approximately one and five-tenths times that of "914 One and one-half times as many fixed positive blood Wassermann reactions resulted from the use of neoarsphenamine alone or in combination as from arsphenamine (606) When systems of treatment (continuous, intermittent, irregular) were compared, "606" maintained its efficiency ratio of better than one and one half as compared with neoarsphenamine (35.9 per cent *versus* 20.5 per cent) ultimate good results under continuous treatment. Under intermittent treatment the lead of "606" was somewhat less pronounced and in irregular treatment there seemed to be relatively little choice The category of ultimate results included cured with examination, cured without reexamination, patients placed on probation, relapse or resistant serology and reinfection.

Undoubted consolation for the comparative showing made by neoarsphenamine was obtained from the Cooperative Clinical Investigation, which showed that the two drugs approached equality when used with the heavy metals 13.6 per cent of "606" reversals to negative in the first three months, as compared with 10.9 per cent "914 reversals; and 33 4 per cent reversals *versus* 35.7 per cent for the same combinations in four to twelve months. Thus, though neoarsphenamine is slow in securing reversal at the outset it catches up with arsphenamine when used in combination with heavy metal No superiority is apparent on the part of the bismuth combinations as compared with the mercury combinations. Neoarsphenamine, although it catches up with arsphenamine in the serologically reversible case, loses ground seriously in the long run in its failure to prevent fixed positive Wassermann reactions and Wassermann-fastness. This same question may ultimately have to be raised for the arsenoxides Reaction comparisons between the two drugs carried out by Cannon and Karelitz, by the Cooperative Clinical Group, and by Cole's examination of Western Reserve University clinic material, has tended to indicate that arsphenamine "606, originally considered much the more toxic as compared to neoarsphenamine is in reality perhaps under modern methods of manufacture, a very close second, and even from the standpoint of late serious reactions, superior to neoarsphenamine The figures are summarized in the text of the second edition.

Mapharsen.—Ehrlich discovered arsenoxide comparatively early in his studies but he and his associates (1910) felt that while arsenoxide was highly spirocheticidal it was too toxic for clinical use. This view was strengthened by Voegtlin and his coworkers (1923) who found that the increased toxicity of the arsphenamines on standing was due to arsenoxide. Rosenthal and Probey (1933) also showed that the toxicity of the compound was ten times that of arsphenamine Interest in this preparation was reawakened by Tatum and Cooper (1934) who found that in experimental syphilis its chemotherapeutic index was high. These findings were confirmed by Gruhzit (1934–35) but not by Raiziss and Severac (1935) By a reduced dosage schedule the drug was then introduced into clinical practice

The revival of arsenoxide (mapharsen) by Tatum and its application to the general therapy of syphilis by his clinical associates Lorenz and Foerster

(1935 1937) and also in mass study by Gruhzit and Dixon (1938) is probably the most important single contribution to the arsenotherapy of syphilis since the introduction of neoarsphenamine. Judged by the short-term elements in the standards of evaluation Stokes and Beerman (1941) state that arsenoxide (mapharsen) *has met every requirement. It is rapidly spirillicidal and convincingly* effective in the healing of lesions, reduction of serologic tests to negative, and other forms of symptomatic response. For the length of time it has been in use it has an excellent record in the prevention and control of *asymptomatic* neurosyphilis The bibliography of the drug is as yet deficient in thoroughgoing study of infectious relapse In late syphilis of special systems it is at least as effective as the arsphenamines in late syphilis of the nervous system, no more and no less effective Its worth in pregnancy is probably though not as yet demonstrably that of the arsphenamines though Castallo, Coppolino, Rakoff Roeder and Dickson (1939) in a group of 110 pregnant women, treated with mapharsen and bismuth rated the drug definitely less effective than neoarsphenamine in the treatment of syphilis in pregnancy because it does not afford as good protection to the fetus during the period of treatment, and complications in the mother especially gastrointestinal, are more frequent than they should be. Morgan (1938) treating congenital syphilis, rates it more effective in reversing serologic tests than any other arsenical compound previously used. Cornell and Astrachan (1938) gave the drug intramuscularly and refused to draw conclusions as to its effectiveness on account of the low dosage employed. Howles (1939) found this drug good in his experience in treating 204 congenital syphilitics. Chargin and Leifer (1938) treated 50 consecutive Wassermann-fast patients with mapharsen, to find that the drug is neither more nor less effective than any other arsenical in the management of this type of patient. Cole and Palmer (1937) in a careful study of 242 patients of whom 185 were in the primary or active secondary stage, employing a total of more than 5000 injections, apparently rate the drug as approximately *the equal of the more familiar arsphenamines. There is a notable* absence in the literature of comparative series run in similar conditions in the same clinics, using mapharsen parallel with the older arsenicals.

One of the strongest talking points" for mapharsen is the undoubtedly greatly reduced incidence of reaction to this drug Nitritoid crises, often a serious annoyance with the older arsenicals, is all but absent with mapharsen. Epstein (1941) compiling data from 92,000 mapharsen injections, found skin reactions, including exfoliative dermatitis, from one-half to one-third or even one-ninth as frequent as with the standard arsenicals. This is especially true of exfoliative dermatitis. Rein and Wise (1939) listed nineteen types of reaction recorded to 1939 including practically everything made familiar by the older arsenicals except aplastic anemia, of which at the time of their writing there was not a single recorded case but which has been subsequently reported (Kirkham and Perlmutter 1941) They report one death, but fatal accidents are certainly extremely few One of the strongest tributes to the low toxicity of arsenoxide is the experience of the Hyman Chargin, Leifer group and many others working with massive arsenotherapy in which substitution of mapharsen in total dosage as high as 1200 *mg* has not served to approach the toxicity of neoarsphenamine in an average dosage of 4 Gm. (4000 mg.) On the staying power of mapharsen very little is as yet of necessity available. Colonel Harrison (personal communication) has expressed the opinion that the most serious deficiency of mapharsen will be in the direction of permanence of

results (see Chapter V) Taking into consideration all the various factors entering into the efficiency of an arsenical it seems reasonable to expect that as in the case of neoarsphenamine any existing intrinsic deficiencies will be taken up in the modern systems of treatment by the use of bismuth as a heavy metal bringing the level of effectiveness of combined mapharsen-bismuth therapy fully up to the standards achieved by the conventional arsphenamine and neoarsphenamine therapy by a combined continuous (CCG) therapeutic systems

Always more or less parenthetically but nonetheless usefully it should be pointed out that mapharsen is a valuable substitute for other arsenicals when these have proved reaction-producing in the individual case Reports on this matter include those of Jordon and Traenkle (1937) Goldberg (1939) Schoch (1940) Epstein and Falconer (1940) Falconer and Epstein (1940)

Sulpharsphenamine —This drug exhibits the curious paradox of warm allegiance on the part of some undoubtedly competent observers side by side with damnation from others equally competent. Stokes and Behn pointed out the phenomenally high incidence of hematopoietic and dermatitic accidents with the high therapeutic effectiveness predicted by Voegtlin Relatively non reaction-producing and therapeutically effective when given to children, it has been subjected to so much criticism on the score of grave reaction produced in adults that its status was reviewed by the Council on Pharmacy and Chemistry in 1932 and the *pros* and *cons* there discussed. The late Dr Albert Pfeiffer (1935) who strongly supported its continued general use by the New York State Department of Health compared the reaction incidence in 29,510 in ections with the statistics of the Cooperative Clinical Group insisting that sulpharsphenamine s record was fully equal to that of the other arsphenamines. He stated that in the New York State Clinics, there were no cases of aplastic anemia, cerebral hemorrhage acute yellow atrophy or ocular damage and no deaths from the drug. Osborne Rickloff and Butler (1933) in parallel tables showed that the incidence of jaundice was 1 in 800 injections for arsphenamine (606) for sulpharsphenamine 1 in 179 injections Dermatitis occurred in 1 of 850 injections following arsphenamine whereas it occurred in 1 of 298 injections following sulpharsphenamine. There were no cases of purpura following arsphenamine whereas two followed sulpharsphenamine. The United States Navy Medical Department (1940) using sulpharsphenamine from 1925 to 1939 among 20 438 injections, reported 17 mild 8 severe and no fatal reactions to sulpharsphenamine During the year 1939 943 doses of this drug were administered with no reactions whatsoever In the fifteen year period the incidence of reactions of 1 to 1178 doses of sulpharsphenamine is somewhat higher than the average ratio of 1 to 1470 doses of 8 arsenicals trivalent and pentavalent. In general it is clear therefore that the weight of opinion is opposed to the use of this drug in adults, but sanctions its use in the treatment of children

Bismuth Arsphenamine Sulphonate (Bismarsen—Bismuth Sulpharsphenamine) —This drug synthesized by Raiziss in 1925 contains 12 to 15 per cent of arsenic and 23 to 25 per cent of bismuth It should never be given intravenously and when given intramuscularly is dissolved in 1½ cc. of distilled water containing a local anesthetic *The combination is a rational one and* Kolmer has found that the trypanocidal activity is greater than that of "606" in equivalent doses of arsenic, thus supporting the contention of Lehnhoff Wyld that the activity of an arsenobenzol compound is increased by the

presence in the circulation of another metal. It is important to emphasize the fact that the drug can and should be used continuously for long series if its best qualities are to be brought out, and that the interval between injections where maximum effect is desired should not be greater than three or four days. When these requirements are overlooked or disregarded relatively unsatisfactory results are sure to follow. The series of injections in the more recent work of this drug frequently number 60, 80 or even 100 in length and should not be broken up into courses or interrupted by other methods of treatment.

The advantages of the drug include: (1) Exclusively intramuscular administration with comparatively little local reaction and measurable therapeutic effect, in many cases, with injections only once a week (though in early syphilis 2 injections a week are desirable); (2) susceptibility of administration in long courses; (3) very low incidence of complications attributable either to arsphenamine or bismuth, which makes the drug a valuable substitute for the other arsphenamines that may have set up reaction in a given case; (4) a very high proportion of lasting good effects on the blood Wassermann reactions; (5) low incidence of neurosyphilis when the technical precautions above described are strictly observed in early cases; (6) absence of therapeutic shock and paradox in cardiovascular and hepatic syphilis, provided the initial dosage is very small (0.05 Gm.) and (7) ease and simplicity of preparation for administration.

The disadvantages include (1) a slower spirillicidal effect than that of neoarsphenamine, though more rapid than that of some bismuth preparations. This delay is sufficient to justify beginning treatment in early syphilis with a more rapid spirillicide such as arsphenamine, for the first 1 or 2 injections. (2) The drug is not absolutely free from complications and shows possibly somewhat more tendency than neoarsphenamine to give rise to aleukemia hemorrhagica. Jaundice and dermatitis are however very rare complications of treatment with this drug. (3) Local reaction after injection is sufficient in some cases (8.2 per cent) to compel a change to another drug. The drug is fairly effective against symptomatic late syphilis but (4) practically ineffective against the serological changes; and hence cannot be particularly recommended for use in this field. In prenatal syphilis the results are still under discussion but have not thus far been striking in the older latent cases. In latent Wassermann-fast acquired cases, bismuth arsphenamine sulphonate presents no intrinsic advantages not obtainable by varying the mode of treatment with other combinations. It may be said, however, that the drug, in combining both the arsphenamine and the bismuth phase of treatment, accomplishes in one motion what ordinarily requires two, with less risk of complications and better general tolerance of a prolonged though moderate treatment regimen.

The original paper by Stokes and Chambers, reporting two years' experience with the drug, has been followed by other studies, some condemnatory (O'Leary and Brunsting), and others commendatory of its use in certain phases of the disease. Kolmer, who more nearly approached our methods in the treatment of early syphilis than did O'Leary and Brunsting, obtained, on the whole, very good results. Tobias, and Haddon and Wilson have found it very useful in tabes for the relief of pain especially. W (Stokes, Miller and Beerman, after five years) were particularly impressed with its usefulness in cardiovascular syphilis and when it is possible to give it with sufficient intensity the results in early syphilis, in our opinion, compare very favorably with those obtained by the older drugs. Our early confidence in this drug has been reaffirmed by a review of fourteen years' experience (Beerman, Shaffer and Livingood, 1942). Haddon and Wilson rated the drug as superior to tryparsamide except for tonic effects in the treatment of tabes. De Shivers had excellent results in early syphilitic meningitis. Rabies and Severac reported on its efficiency in experimental syphilis.

Silver Arsphenamine and Neosilverarsphenamine.—These drugs, put forward by Kolle during the first World War, have slowly achieved a recognized place in syphilotherapy, although the first burst of publication has not been followed up by much elaborate or detailed study. Silver arsphenamine especially continues to be used with accumulating evidence that it is really from the therapeutic standpoint one of the most effective of the arsphenamines. Cannon (1031), in comparing it with arsphenamine and neoarsphenamine, found serologic tests reversed in a fewer number of injections of silver ars-

phenamine a smaller amount of the drug and a slightly shorter length of time than the neoarsphenamine. Its superiority over neoarsphenamine was apparent also in the healing of lesions and in the achieving of satisfactory end results it stood only very slightly below neoarsphenamine The fear of argyria which has had an important influence on the use of this drug is well grounded Pillsbury and Hill (1939) collected 10 cases of argyria from the use of silver arsphenamine In their summary it stands third among all silver compounds responsible for argyria. While this incidence is not intrinsically high in proportion to the use of the drug the complications are so disconcerting and medicolegally serious as materially to discourage the use of the drug

Spiegel states that it is inadvisable t give more than 8 Gm. of the drug as total treatment if argyria is to be voided. The dosage of silver arsphenamine is for women not in excess of 0.2 Gm. and for men from 0 25 to 0.3 Gm.

Solusalvarsan; Thioarsene; Triosdarsen.—These three trivalent arsenicals have received considerable study in recent years. Solusalvarsan (*Acetyl-glycarseno-benzene*) was found to be relatively ineffective and reaction-producing (Harrison, 1939 Guy Goldmann and associates, 1940)

Thioarsene likewise was rated as unsatisfactory by various investigators (Robinson and Moore (1935) and others)

Triosdarsen (trisodium salt of 3,3' diamino 4 4 dihydroxyarsenobenzene N N d methylene sulfoxl acid) ha had an extended and carefully conducted clinical trial t the hands of the Syphilis Clinic of the University of Pennsylvania (1937 1940) and of Givan and Villa (1939) in the Pediatrics Department of the Long Island College of Medicine, and the Brooklyn Eye and Ear Hospital. The former authors found the reaction incidence compared with several other series, including arsphenamine neoarsphenamine and mapharsen, to compare favorably with and even to be lower with respect to mild reactions than that of most of the named drugs. With respect t severe reactions, there was some tendency t increased frequency of dermatitis and hemorrhagic reaction, as previously observed in most of the sulfarsphenamine group of drugs. The distinctive characteristics of triosdarsen include superiority to neoarsphenamine with regard to the rat of healing of primary and secondary lesions, and effect on the serologic reactions of the blood, intermediat between neoarsphenamine and arsphenamine: an exceptionally low incidence of asymptomatic neurosyphilis as evidenced by spinal fluid examination. In subsequent investigations covering period of eight years, this position has been reasonably well maintained. It would appear that the superior clinical effectiveness of the drug must be measured against an undoubted tendency t dermatitis and hemorrhagic reaction, which is relatively rare with mapharsen for example. Givan and Villa, employing triosdarsen in congenital syphilis, reported it well tolerated by the intravenous and intramuscular routes, and particularly free from paravenous infiltration hen the drug as delivered outside of vein. Gastro-intestinal reactions are more numerous than the verage, but are ttributed by these observers to fright on the part of the children. The drug can be substituted in patient having reactions t neoarsphenamine. It was markedly effective in the treatment of interstitial keratitis, and an unusually high reversal of positive Wassermann reaction (76 per cent) was secured by the use of the drug alone or in combination with other drugs. The tonic effect as notable.

THE PENTAVALENT ARSENICALS

Tryparsamide.—This drug, the sodium salt of N phenyl-glycineamide-p-arsonic acid was synthesized by Jacobs and Heidelberger of the Rockefeller Institute in 1917 It is a white, odorless, crystalline substance readily soluble in water and contains 25 1 to 25.5 per cent of arsenic. Tryparsamide is a relative of atoxyl and derives its therapeutic efficiency and toxic peculiarities, fortunately much reduced, from that fact.

Historical.—For drug in many respects so remarkable, tryparsamide has had slow acceptance in the therapy of syphilis. Thoroughly investigated from the toxicological and pharma

cological standpoint by Brown and Pearce in 1919 It was supplied by the Rockefeller Institute to the Wisconsin group of psychiatrists and pharmacologists, Lorenz and Loevenhart and their coworkers, who in 1923 published the first extended clinical report of its application in its present field, that of neurosyphilis and particularly paresis. Over a period of several years, the Rockefeller Institute maintained control of its distribution and its manufacture was carried out under license by only one concern, Merck & Company The steadily growing clinical experience has now clearly established the fact that the one serious complication (ocular) is controllable, and that prolonged continuous and not casual, intermittent use, is the secret of success with it.

Pharmacology and Toxicology of Tryparsamide.—Brown and Pearce showed the minimum lethal dose for different types of animals to be 0 75 to 2.75 Gm. per kilo a positively unprecedented low level of toxicity for arsenicals with such striking therapeutic efficiency Toxic effects do not begin until relatively close to the minimum lethal dose and recovery from toxic manifestations below the lethal dose is rapid and complete. The drug is remarkably noncumulative in contrast to other arsenicals, and repeated large doses may be given at short intervals without injurious effects. A definite tolerance for it may also be developed All of these findings have been confirmed for man.

The great theoretical interest of tryparsamide for syphilotherapeutics lies in the fact that while it is one of the most powerful trypanocides known, it is only slightly spirillicidal (1–1 or 1–2 as compared with 1–7 or 1–10 for arsphenamine) and will not destroy the *Spirochaeta pallida* to any marked degree in any lesion of the disease. Brown and Pearce in suggesting its use in syphilis, laid emphasis, not on its direct chemotherapeutic effect, but on its tonic action and resistance-building power Subsequent studies by Voegtlin, Smith, Dyer and Thompson employing an ingenious method of testing the penetration of drugs into the cerebrospinal system by studying their action, when intravenously injected, upon trypanosomes introduced into the spinal canal, showed that no small part of the secret of tryparsamide efficiency lies in its extraordinary ability to penetrate the nervous system through the meninges.

Tryparsamide was the most effective of nine arsenicals used, an amount equal to only 4 per cent of the minimum lethal dose being 87 per cent efficient. Mehrtens, Kolos, and Marshall found tryparsamide to be positively chemotropic for nervous tissue as compared with arsphenamine. The spinal fluid of patients who had received previous injections of tryparsamide showed as much as two or three times as great an arsenic concentration as those who had received intravenous arsphenamine injections. The arsenic content of the blood after intravenous injection was studied by Fordyce, Rosen, and Myers, who found that the drug disappeared rapidly from the blood stream, only traces remaining at the end of seventy-two hours, a fact which apparently led them to discount its efficacy

The rate of elimination of tryparsamide is extremely rapid, the relatively enormous dose being excreted, as shown by Young and Muehlberger, to the extent of 68 to 85 per cent within the first twenty-four hours. At least part of it seemed to be excreted unchanged (Young and Hamilton), within twenty-four hours, by the kidney

The distribution of tryparsamide has been shown by Osborne microchemical studies of tissue to be essentially that expected of pentavalent arsenicals, namely high concentration in the nervous system, though the distribution in the rabbit was somewhat uneven and an exemption of the lungs, heart, liver and adrenals was noted. After a lethal dose the drug was demonstrated in sympathetic nerve ganglion and also in the walls of the stomach. Osborne concludes that at the end of an hour following large dose, some arsenic has already penetrated into the nervous system; that the liver is evidently a negligible factor in the metabolism of the drug and that tryparsamide is rapidly excreted through the kidneys and the entire intestinal tract. The increased retention of the drug in the liver late after a lethal dose is interpreted by Osborne as due to primary injury with secondary degenerative effect.

Young and Loevenhart give as the biochemical reason for the production of optic nerve lesions by tryparsamide the general rule, applicable to all arsenicals, that the presence of the amino groups in the para position to the arsenic, regardless of its valence, induces tropism for the optic nerve.

Reactions to Tryparsamide.—Both immediate and delayed reactions to this drug are relatively uncommon as compared with those produced by the trivalent arsenicals. Several reports indicate that there has been a recent tendency for the preparation to induce an increasing number of systemic reactions (Hinrichsen, 1939 Kopp and Solomon, 1940 Beerman and Shaffer 1940 Downs McDermott and Webster 1941) Optic nerve injury continues to be the chief concern of those using this drug. Tryparsamide causes about eight times as many permanent ocular complications in those with damaged eyes before treatment as it does in those with normal eyes before treatment (22.7 per cent and 2.9 per cent respectively Hinrichsen, 1939)

Details of the therapeutic action and side effects including ocular reactions to tryparsamide will be discussed fully in the Chapter on Neurosyphilis.

Acetarsone (Stovarsol, Spirocid)—This is the American official name for pentavalent arsenical with apparently definite spirillicidal activity especially adapted for oral use It is a white crystalline substance, the sodium salt of 3-acetylamino-4-hydroxyphenylarsonic acid. It is dispensed in tablets of 0.25 Gm. each. I spite of the large experimental and clinical literature on acetarsone, summarized in the second edition of this text and in the excellent compilation by Hinrichsen (1942), this drug has not been widely accepted for prophylaxis or treatment of acquired syphilis. Some pediatricians have, however been inclined to consider this drug valuable for congenital syphilis. In the outstanding study by Pillsbury and Perlman (1935, 1939) it was shown that the effect of acetarsone in arresting congenital syphilis is inferior to that of arsphenamine and bismuth preparations the incidence of reactions is high the drug cannot be controlled by experimental studies of spirochetícidal action and toxicity in animals, and it is probably not administered as directed to patients treated at home. For those who wish to use acetarsone it is recommended that the following schemes be employed

For Adults. (*Prophylactic—Non-intensive*) —4–6 Standard tablets daily for three to five days with four to five days of rest between courses. The total dosage is 24–90 tablets (6–22.5 Gm.)

Intensive 4–6 tablets daily for five to seven days with three, later five, days of rest between courses. The total dosage is 100–210 tablets (25–52.5 Gm.)

Therapeutic 4 tablets day seven to five days (total, 49) with four to eleven days of rest (total, 48) Total dosage is 196 tablets (49 Gm.)

For congenital syphilis The system of Bratusch-Marrain was considered by Pillsbury and Perlman as the best available It is low dosage intermittent continuous scheme as follows:

1st week—7 days—0.005 Gm. per kg. daily
2nd week—7 days—0.010 Gm. per kg. daily
3rd week—7 days—0.015 Gm. per kg. daily
For next 6 weeks —0.020 Gm. per kg. daily
Rest for 4–6 weeks.

These courses are to be repeated until the Wassermann reaction, which is taken after each course is negative three times in succession.

Treparsol and Acetylarsan.—These two drugs, the former being the formyl derivative corresponding to stovarsol, which is the acetyl derivative of amino-hydroxyphenylarsonic acid has been employed by Simon, Flandrin, and others with results thus far neither convincing nor satisfactory Gougerot and Lacapere cautiously suggest its use as tapering off treatment. Acetylarsan, the diethyl ammonium salt of stovarsol, may be administered intramuscularly or subcutaneously and was strongly commended by Lacapere and Laurent. These investigators, however rate it as inferior to the arsphenamines and only usable in occasional cases of intolerance of the latter Neither drug has gained any foothold in American practice nor is there any apparent reason at this time for its doing so

Aldarsone.—This pentavalent arsenical synthesized by Raiziss has been studied in the treatment of neurosyphilis by Kamman (1938) and by Spiegel, Leifer and Sarason (1941). It is related chemically to acetarsone and is a condensation product of 3-amino-4-hydroxy-phenylarsonic acid, with sodium formaldehyde sulfoxylate. It is a white crystalline powder containing about 17 per cent arsenic. It is highly soluble in water; the aqueous solution is pink and has a pH of about 7.0. According to the experimental material of Raiziss and his coworkers, aldarsone is more spirochetícidal than tryparsamide. The drug is dissolved in 10 cc. sterile distilled water. The first dose should be 0.5 Gm., subsequently increased to 1 Gm. intravenously at weekly intervals. Only rarely have objective or subjective visual disturbances been observed in patients treated with this preparation, even in those who had previous optic nerve damage (Spiegel *et al.*) or who could not tolerate other pentavalent arsenicals because of visual disturbances. This compound should be given in long courses, similar to those for tryparsamide. Aside from its value as a substitute in cases intolerant of other pentavalent arsenicals, aldarsone is effective in the treatment of neurosyphilis. This therapeutic efficiency has been affirmed by Bennett, Morrison and Modlin (1944) who used aldarsone combined with artificial fever. This combination, however, may produce neuro-ophthalmic complications.

CHAPTER VIII

TECHNICAL METHODS AND CONSIDERATIONS IN DIAGNOSIS AND TREATMENT

General Considerations the Importance of Technic.—The greatest emphasis necessary at the present day in the practice of medicine with respect to the treatment of syphilis is on technic For the physician is constantly bringing modern methods into disrepute through manipulative error and is inflicting injury and failing to cure his patients through his inability to carry out what he attempts The preparation of water the preservation of asepsis, the technic of mixing and the manual and other manipulation of successful administration should be learned for private as for clinic practice. Any physician who administers treatment without personal knowledge and control of these factors may expect trouble. Responsibility can be delegated to properly trained technicians, but even here knowledge necessary to supervise them should be part of the equipment of the physician for the work.

Treatment Room Arrangement and Equipment.—While it is not indispensable to have tiled floors and walls, or the most costly of operating room furniture or even to have a separate room for treatment work, the physician who is called upon to treat much syphilis will find it distinctly advantageous to develop special surroundings for the purpose and the clinic is obligated to do.

The convenience and accustomedness of such working environment adds greatly to technical smoothness and efficiency It assists in maintaining the morale of the patient, and in impressing him in an entirely legitimate y thout frightening him, with the seriousness of his infection and the importance of giving his best cooperation to the effort which is being made t get him well The effect is not unlike that of the well-regulated sanatorium on the tuberculous patient The physical equipment and surroundings of some dispensaries and private offices have as much to do ith the difficulty of holding patients to treatment as do any inherent derelictions of the patients themselves. W have seen enough of the effect of paint clean furniture, organization, and spirit in reviving drooping clinic or building one from small beginnings, to ppreciate that in this aspect of medicine in business, reasonable investment in equipment and personnel brings its return.

The attitude and reactions of the personnel impart as much to the successful operation of a service for syphilis, or an individual practice as does the equipment and the technical skill. Amenities are not mere foibles, but rather the outward evidences of an inward surefootedness, competence and humanity

Cheerfulness, personal friendliness ithout effervescence, the individual rather than the mechanical tone of voice, are technical essentials. The addressing of the patient by name, the recollection of personal details of his case hich shows him that the operator knows who he is and something about his troubles, are invaluable assets in effective treatment work. The patient should never enter the treatment room ithout receiving greeting and smile, if the highest degree of confidence and cooperation is to be obtained

Arrangement.—The light in the treatment room is as important as in the examining room and should conform herever possible t the same criteria. Placement of the table and the position of the patient should be such that no shadow are cast upon the field of work. I intravenous injection it is an advantage t have cross light, hich may bring out the slight elevation produced by an otherwise invisible vein.

A treatment room arrangement which keeps the patient away from sterile tables, solutions and operator and at the same time gives the nurse freedom to control his movement, guide him in and out, reach her sterilizing solutions and bandages and assist the operator without contaminating his field, is a decided advantage

Assistance.—The staff necessary for the operation of a single treatment unit or for private office work need not exceed, in addition to the physician, one unsterile assistant for arsphenamine administration, one or two for all forms of spinal work. It is possible to develop a one-man technic for general or occasionally special practice but it is much more wearing on physician and patient and unsatisfactory if time is important or the niceties of technic are to be observed We do not believe however that spinal puncture should be done on any patient by an unassisted operator even though the patient may be well trained.

Intensive arsenotherapy requires special preparation which will be mentioned later *Military practice can be organized along hospital lines with* individual variations dependent upon circumstances

Asepsis.—The physician will be spared more than one pang of conscience and anxious moment if he can always look backward in his analysis of his own procedure upon the strictest adherence on his part to the principles of asepsis. Clean water long boiling vigorous scrubbing aseptic conscience, are therefore commended as selfish as well as altruistic requirements in syphilological work.

CARE AND HANDLING OF EQUIPMENT

Water for Sterilization.—For the smooth working of syphilological technic it has been our practice to advocate the use of distilled water as the starting

Fig. 102.

THE A-B-C OF WATER FOR ARSPHENAMIN INJECTION

1. Know the source of supply and the chemical treatment of the water you plan to distill.
2. If markedly contaminated, much treated, or subjected to softening or chlorinating processes, use in preference purchased distilled water for chemical work from reliable firm.
3. Test the supply and the end-product from time to time by ( ) boiling it down almost to dryness (b) litmus yellow solution for alkalinity (should not turn red) silver nitrate solution, 1 to 2 drops should leave no cloudiness.
4. Don't rush or bump your stills.
5. Take them down and clean them occasionally depending on the amount of water put through them.
6. Cover rubber with block tinfoil (pure tin).
7. Don't save water by boiling still down. Discard the last third in the still and the first and last fifth of the distillate
8. If still boils dry discard all the product and clean thoroughly all parts
9. Protect scrupulously the mouths of flasks and their contents from dust and exposure to any form of contamination.
10. Make no transfers from flask to flask, after last distillation
11. Use no water over twenty-four hours old.
12. Remember all the time, that the product goes into the blood-stream, and handle it accordingly

point of all sterilization by boiling. Coated and discolored glassware, sticking and uncleanable syringes, ill fitting adapters and needle butts can in this way be avoided and much time and labor saved. There are available types of

syringes and other glassware which successfully stand boiling in distilled water and these types are commended as equipment.

Water for Arsphenamine.—Water for solution of the arsenicals is now obtainable in small amounts in ampule. It is not, therefore, necessary for the practitioner using these drugs to install special equipment for the preparation of his own water. Clinics using large amounts of simple distilled water and desiring to set up their own equipment for it, are referred to the second edition of this text, page 35° for a full description of equipment and methods.

Freshness and Preservation of Distilled Water.—When properly put up in ampule, distilled ater as solvent for the arsphenamines ma be used as marketed without reboiling. This is not true, however of larger quantities of distilled water kept under ordinary conditions in operating room and office. These should always be fresh, made up within twenty-four hours, and must be kept preferably in the ice-box in gauze-corked flasks in which the last distillat is caught. The water should not be transferred about from flask t flask. Before use, freshly prepared distilled water must be sterilized by boiling for ten minutes with the gauze cork removed from the mouth of the flask, and when the boiling is complete sterile beaker may be placed over the mouth and neck of the flask. This is preferable to reinserting stopper.

Glassware.—Glassware used for syphilological work should be heat resistant, preferably Pyrex.

For Neoarsphenamine and Mapharsen Administration Intravenously:

2, 2-ounce heavy-walled medicine glasses.

1 10-cc. or 20-cc. (according to preference) all-glass syringe resistant to boiling in distilled water piston ground t perfect fit.

For Intramuscular Administration of Arsphenamine Derivatives

Only the 2-cc all-glass hypodermic syringe is necessary and the ampule or glass of distilled ater the dissolving being done in the ampule (see Figs. 117 120)

For Tryparsamide Administration.—The same set-up is required as for neoarsphenamine unless the drug is dissolved in the ampule, as with the intramuscularly administered arsphenamines.

Cleansing of Glassware.—Glassware should be washed in green soap and hot water when first purchased, and thoroughly rinsed after each subsequent use. Accessible articles should be swabbed out with a piece of gauze and Florence flasks may be cleaned by agitating in them with a rotary motion mixture of glass beads and scraps of filter-paper in small amount of water. Repeated rinsing in very hot ater followed by distilled water is essential t remove all soap. If pure ethyl alcohol is vailable, this should be used for the last rinsing and the flasks air dried. Denatured alcohol cannot be used.

Autoclaving of Glassware.—Where facilities are vailable glass articles may be wrapped in towels, utoclaved at 20 pounds for half an hour and then baked in the dry oven at 240° C. for one hour. This cannot be done if they have rubber attachments.

Sterilization of Glassware.—All glassware used in intravenous ork should be sterilized by boiling for ten minutes by the clock, after boiling begins, ith water filling and completely surrounding the hollow articles. T immerse flask partly or cover it with wet gauze, in the belief that the steam under the sterilizer lid will sterilize, is mistake. It is economy and safety combined t use distilled water (single distillation) for boiling up glassware, since the deposits of salts and dirt from ordinary water make future cleanliness difficult, if not impossible waste all the value of precaution in water preparation and reck the syringes with grit. All glassware should be wrapped in gauze to prevent bobbing about in the sterilizer with chipping and breakage. Boiling should be slow violent boiling taking toll in breakage.

Syringes.—The syringe is the syphilologist's rifle and selection and care of it should be meticulous and intelligent. Glass syringes should have special care since they are expensive and easily broken. Those which quickly lose the perfection of fit as between piston and barrel do not qualify for satisfactory syphilological work.

Syringes and containers must be carefully cleaned for they accumulat considerable deposits nd surprising residues of the drugs and biological fluids which have passed through them. The

piston and barrel should never be allowed to become separated if several are in use. In boiling the piston is removed and placed side by side with the barrel in gauze wrappings held by properly prepared rubber bands, which prevent both direct contact or bumping. The tip or nozzle of the syringe should be carefully protected in all handling. T "try the suction by putting the finger over the end of the syringe nozzle, while traction is exerted on the piston, costs several syringes mouth when the piston slips from the fingers and flies back. Such maneuver is seldom necessary if proper glass is used and syringe barrels and pistons are not allowed to become mismated. Eccentrically placed nozzles are preferred by some. Glass-metal combinations and elaborate locks are unnecessary though popula both in European and American practice.

Special Precautions.—Schoch's demonstration that enough bismuth arsphenamine sulphonate, for example, is retained in rinsed syringe which has not been thoroughly cleaned, to cause an arsenical dermatitic reaction in patient once sensitized to the drug is in point. The bore of every syringe should therefore be cleansed with cotton wound applicator used as a ramrod and sticky or oily preparations with bismuth residues may well require syringes reserved to their exclusive use. The treatment room chief should inspect the nozzle of the syringe at the point where the needle shoulder comes in contact with the glass, and if any residue can be seen or picked loose with pin, there should be general overhauling of the nursing technic. The junction of the barrel and the end should also be atched. There should be little or no discoloration in properly cleaned glassware. Syringes used for blood dra ing should be immediately rinsed in cold water; if this is mpossible pull the plunger back half-w in the barrel to prevent sticking on coagulation, and clean as soon as possible.

Rubber Including Gloves.—The proper care and preparation of rubber goods before use is essential not only as a matter of economy but because very serious reactions as well as contaminations of solutions and instruments may result from a casual technic. This applies especially to tubing as described below

For the technics here described the rubber articles used consist exclusively of gloves, condenser tubing, corks for condensers, special corks for blood containers in intraspinal work, and the rubber tubing used in connecting needle and container in the gravity administration of the arsphenamines.

All rubber regardless of its use should be as nearly "pure gum as possible, black or transparent yellow (acid-cured) in color and should be prepared, with the exception of gloves, by soaking over night in 5 per cent sodium hydroxide solution in order to prevent "tubing reaction (see p. 296) care being taken to see that the lumen of the tubing is completely filled and washed through with the solution. A crop of tubing reactions appeared on our service even after the published description of the reaction, through the failure of an inexperienced nurse to fill the lumen of the new lot of tubing. After soaking and rinsing, the tubing may be ttached to the containers and sterilized by boiling. Tourniquets and compression bandages require no sterilization unless they are handled by the operator under one-man technic, in which case they should be treated with alkali when new and boiled up with the apparatus.

Sterilization of Rubber Gloves.—The rubber glove is an essential item in the best aseptic technic of syphilological treatment in our estimation, though perhaps this is, with neoarsphenamine or mapharsen for example, an unnecessary refinement

Rubber gloves for asepsis should not be boiled up with the glasses for arsenicals. Dry sterile gloves are decidedly preferable to wet because of the disagreeable and dangerous trick that the wet glove has of leaking contaminated solutions or water over apparatus and int containers and mixing flasks. Gloves should either be boiled for ten minutes, wiped dry powdered with sterile powder and wrapped in sterile wrappers by an attendant under aseptic conditions, or be boiled, dried, powdered, and autoclaved in loose wrappings t 15 pounds pressure for thirty minutes After use, all rubber gloves should be thoroughly cleaned from blood stains, dried and searched for pinholes before being sterilized. T give an examiner or operator pricked glove in syphilological as in surgical work is crime. While these precautions seem part of an elementary technic, it is surprising how much vigilance it takes to carry them through. The physician working alone can scrub up and prepare half dozen pairs of dry gloves at time with less trouble than he goes

through in boiling up and dragging on six pairs of wet ones. In syphilological examinations, f course sterile gloves are rarely necessary

The Gauze and Cotton.—Gauze and cotton must be of the finest type, free from bleaching preparation and sizing of any kind, of long fiber and free from dust or lint.

Cotton Filtration of Solutions.—Loren Shaffer has injected lint-containing solutions into rabbits without apparent ill effects, so that this element in the production of embolism is probably exaggerated, but should, none the less, be carefully w tched in treatment room practice. Solutions which contain obvious shreds of lint should be refiltered through the wet filter W have never seen an embolism from intravenous injection of nonirritating and properly prepared solutions, and believe that this explanation is more often an excuse than a fact.

The Needles.—The needle is a surgical instrument, although its long association with the tailoring trade and the pin cu hion in our minds has perhaps not been the best way to impress us with the fact. Good technical results in syphilotherapy are materially furthered by close attention to minute details in the care and handling of needles, and serious accidents may sometimes be averted by very simple precautions.

Fig. 103.—Testing spinal needle before sterilizing The stylet is removed.

Choice of Needles.—As much care should be given to the choice of needles as t that of surgical instruments, and only the products of the best manufacturers deserve consideration. With the advent of the rustless steels, the softer alloys hich do not take satisfactory points will be less popular nd the precious metals superfluous. The high-grade steel needle requires proper combination of bendabilit and rigidity and should under no circumstances be brittle. Pitting and corrosion of needles under water boiling conditions should disappear with the rustless steel but corrosion by chemical ction must still be closely atched. The eakest spot in the needle is at the junction of the hub and shaft, nd no needle hose length does not allow liberal margin between the point of verage skin penetration and the hub is quit safe, for it is apt to be lost t once on fracture "Preling and the reaming of gritty material from the bore of the needle with stylet, even in amounts only visible ith lens, warn that the needle has become unsafe Internal pitting and corrosion makes the needle dangerous and even the slightest external roughening makes it painful The shaft of needle therefore, should not be placed under the compression of hemostats, the needle being handled instead by the butt, or hub.

The long steel needle must be springy as ell as resistant t fracture and no needle which will not stand bending through an arc of 30 degrees and return practically t normal, is entirely satisfactory The bore must be uniform and the needle must stand the bending strain all the way out t the point (see Fig 103)

Gauge Saf ty Comfort and Speed.—*The gauge of needles must be selected on the basis of* the safety factor; the rat of flow or delivery required the amount of discomfort caused in introduction. The tendency i to forget the first in thinking of the other t factors, especially in spinal puncture needles. An additional factor of technical unfitness arises in the hairline but unbreakable needles hich it sometimes proposed to use bet een the vertebral spines Their

bendability makes them difficult to use. On the other hand, mere thickness does not make needle safe, for the resistance offered by thick needles is greater than that of thin needles. Rigidity or directability is important and here the coarser needle has the advantage over the finer needle. The caliber of the bore not the thickness of the wall, is responsible for the fluid delivery of the needle and should be watched. The wall, not the gross diameter of the needle must be thick enough for safety

Discomfort in the introduction of the needle can be mitigated by the use of local anesthesia with larger needles, but is easily forgotten with those of medium gauge The development of "needle shyness" in patients indicates that this is a distinct factor in their willingness t persist in treatment, and every effort should be made to eliminate these seemingly minor discomforts For this reason, should like to emphasize the utility of the 26-gauge 1-inch hypodermic needle by experienced operators as productive of markedly less discomfort for the patient and as usable in the majority of syringe procedures in intravenous work. A little special aptitude must be developed, but once it is acquired the patient appreciates it.

A small-bore needle such the 26-gauge hypodermic, has importance in forcing the hurried operator to reduce the speed of his i jection. Inasmuch as excessive speed is one of the principal

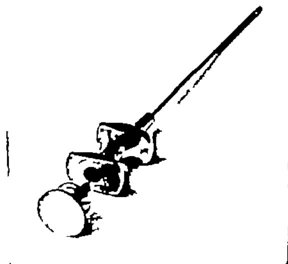

Fig 104 —Detail of the Bier hub. When the stylet is properly seated in the needle the notch in the shoulder engages the pin in the end of the hub

factors in reaction with neoarsphenamine, the small needle tends to prevent trouble on this important score.

Importance of the Stylet.—Stylets should be furnished with all hollow needles and used not discarded.

The occluding or obturator stylet such as is used in spinal needles should be of the same material as the needle, perfect fit, and polished so as not t score the bore. The cleansing stylet need not fit so closely and is usually softer ure of noncorroding alloy It must be long enough to extend beyond both point and hub for effective handling, and rigid enough to stand repeated forcing through the needle ithout buckling or kinking

The occluding stylet of the spinal needle being fitted to the needle and ground ith it should never be separated from it and may be numbered t match it The t should lie side by side, be picked up and laid dow together and fastened or wrapped together with gauze in sterilization Good result cannot be expected where these precaution are neglected.

The Needle Hub.—The hub is the handle of the needle and deserves more than merely passing consideration. If the needle itself is to be handled in the manipulation, the hub should be large enough and heavy enough not to be constant source of irritation. The Luer hub and the majority of cylindric hubs are technically suited only to use ith lever such as that afforded by the syringe to which they are fitted T use Luer needle by direct manipulation seems need

lessly difficult. If the needle is t be handled direct, as in spinal puncture, it deserves suitable h b. T handle any needle by the shaft because the hub is unsatisfactory sacrifices fundamental principle of needle asepsis—never to touch the shaft, even with sterile gloves. For these reasons, all the needles on our service that are handled direct and not through the intermediation of syringe or tube have Bier hubs (Fig. 104) or should be fitted with guard as in the Fordyce or the Schreiber needle. A rubber tube may be attached to needle hub for routine blood-drawing work.

While hubs are now practically universally adapted to syringes, it is best to use syringes and needles by the same manufacturer if possible. If they do not fit perfectly and invariably without wabbling or aspiration of air or leakage of fluid, the product should be discarded and complaint made Endless vexation will otherwise result. It should not be necessary to use adapters for other than tubing connections. In the purchase of needle it is well t have a syringe or adapter t hand to insure fit, and not to trust t impressions or recollection.

In the spinal needle it is particularly important for the types of point here described, that the obturator stylet be a perfect fit and be held rigid in the barrel. Obturator hubs, carrying pins which fit into holes in the Bier hub, are ultimat ly unsatisfactory because they clog, cannot be kept clean, and ultimately no longer satisfactorily receive the pin which holds the obturator stylet in place. In order to overcome this difficulty longer pin fitting into an open slot in the Bier hub has been developed by one manufacturer and apparently gives more rigid fixation of the stylet while permitting the proper cleaning of the needle.

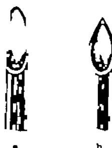

Fig. 105 —a, Rounded needle tip, with cutting edge, which makes an incision in the vein instead of puncture. Less desirable than b, the pointed needle, which inflicts less trauma and diminishes the possibility of leakage

The Needle Point.—The point is to the needle what the edge is to the scalpel and it deserves the same deference and consideration. A five-diameter lens and a good light are indispensable to the proper examination and care of a needle point. In all cleaning and manipulation of needles the point should be protected. The slightest contact of a point with a hard substance unaware may change the next use of that needle from sleight-of-hand to bungling Needles have both point and cutting edge, and the proportion which one bears to the other makes a decided difference for the entered tissue In a technical publication (1017) on intravenous injection, Stokes called attention to the effect of the cutting edge of a needle in producing a leaking venipuncture (Fig 105) Greene, whose spinal needle point is illustrated in Fig 100 has since shown the same thing to be true of dural punctures in spinal work, and his findings were confirmed by Loren Shaffer Bloody arms after vein puncture may therefore be regarded as technical errors and traced to the operator who should be responsible for his needles.

Some common defects in needle points are shown in Figs. 107 108. They are often only detectable by feel or with a hand lens, but they make a decided difference with the patient. It should be recalled that the fitted stylet forms part of the needle point and must be exactly mated to form it, as in the spinal

needle. Such a needle as A in Fig 107 or E in Fig 106 will tear or punch out tissue with pain and leakage as consequences

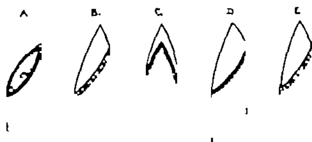

Fig. 106.—(A) The short bevel spinal or cistern puncture needle (B) the Greene or conical point (eccentric) in profile (C) posteriorly (E) shows worn or misfitted stylet which exposes the cutting edge of the needle, cutting or tearing the dura, though a properly made point makes only puncture, with little leakage.

The Greene point for spinal needles (Fig. 100) can be ground from the ordinary flat-bevelled needle by hand on a wheel or stone, or can be specified

Fig. 107.—A, The point of spinal needle with an improperly fitted stylet, such needle tears the dura. B, The proper bevel for spinal needle point. C, The proper bevel for cistern puncture needle.

for the type of needle having the hub shown in Fig 104 Corrosion, which formerly made these very shortlived, can now be avoided by the rustless steel.

The Needle Bevel.—The bevel of a needle point varies with its use Where mere easy penetration of tissue with little discomfort is desired, as in intra

muscular injection, the longer and more lancelike the bevels short of the risk of fracturing or turning the point, the better On the other hand, if restricted space in a tube about the needle point, as within the lumen of a vein or in various parts of the spinal canal forms part of the working condition the bevel must be shortened. In Fig 109 three types of bevel often found on intravenous needles in actual use are shown The first is too blunt for easy entry the second so long it catches in the far side of the vein the third is correct. The longer bevel of the lumbar as distinguished from the shorter bevel of the cistern puncture needle is shown in Fig 107

Needle Sharpening.—Needles do not retain point or edge indefinitely though the fact is easily forgotten. I fact, it is ell to retouch needle to the proper edge and point ith each five to ten punctures. Spinal needles are most satisfactory if touched up before each puncture Retouching ma be needed on an improperly bevelled new needle. In the office, retouching and

Fig 108.—Feathered and "fish-hooked" needle points. The turning of the point may be so slight as only t be detected with lens

sharpening should be done on hard Arkansas oilstone and care must be taken to void feathering or frazzling of the inner edge nd the production of flat bevel The motion necessary t point hollow needle ith suggestion of concavity which should always be present on ne needle, is produced by pressure being brought to bear on first one side of the point and then the other I clinic practice, Colonel Harrison recommends ½-inch finest carborundum wheel with similar-sized lead heel as finisher both being operated by water motor, not by electricity Feathering of the point in sharpening and "fish-hooking" from turning of the point must also be watched The needle should be tested for its "bit" when laid flat on the skin of the hypothenar eminence of the palm. If it takes hold ll there, it will penetrat vein ithout cutting or stripping I sharpening spinal needles, the stylet must be kept forced in, so that the operation requires one hand at the point, the other t the hub.

"Fish-hook" turning of the needle point in contact with hard objects and too much pressure in sharpening ("feather") even when too slight to be seen can be detected by drawing the needle in its long axis on the flat across a piece of gauze. This should be done for all intravenous and intramuscular needles before sterilization and sometimes after if there is any doubt. The resistance and jerky pulling can be easily detected. If in doubt, examine with a lens. Such needles stick, tear and are very painful and may break under "jabbing" and forced manipulation

Care and Cleaning of Needles.—Needles should never be bunched and thrown into solutions but handled individually. After use the needle should be rinsed immediately with some non-coagulable solution, for every time blood is allowed to clot in a needle a certain amount of solid residue is left to plug and favor the retention of moisture and infectious material. In time this material cannot be removed with a stylet. Every needle should be as carefully reamed out with its stylet as if it were a gun barrel. If an aspirator or filter pump is at hand, clean water followed by alcohol and ether should be drawn through the needle to dry it completely. If this cannot be done, alcohol and ether can, with a little care, be poured or tapped through the larger needles by tapping with the finger over the opening in the hub when it is filled with alcohol or ether. The points of needles should in general be sharpened before cleaning, not after (to remove any accumulation from the bore. The external surface of needles should be kept polished with a non-scratching powder, and special attention should be given to the cleaning of the hub with a blunt applicator and gauze. Oil is no longer necessary on rustless steel, but if it is used it should always be removed with alcohol or ether before sterilizing the needle. The unsatisfactory fit of a needle after use may be due, not to warping or manufacturing defects, but to coagulum that has not been properly removed from the hub. The stylet of a spinal needle should be handled in the same way as the needle itself and especially protected from kinking or bending, which then and there ruins the fit at the point.

Sterilization of Needles.—Merely dropping a needle into a disinfectant solution or even boiling it a few moments does not sterilize, as we have been able to satisfy ourselves bacteriologically. The bore of the needle, especially if small, may moreover be unaffected even in boiling because of the contained air bubble. This is especially true if oil be used in cleaning. Alcohol or

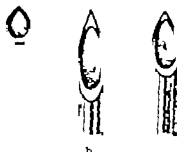

Fig. 100.—Three types of needle point. *a*, Too short; *b*, too long; *c*, correct.

ether should be drawn through just before boiling and should not contain any corrosive or oily denaturing agent. When the needle is boiled, water can thus gain access to all parts of the bore. Such needles should be boiled without the stylets. Sterilization by boiling requires ten minutes and distilled water should be used by preference. Sterilization by baking at 210 C. for forty-five minutes should be used for intraspinal treatment needles, which are wrapped in gauze and sterilized in plugged test tubes. Spinal puncture needles are sterilized by boiling.

Types of Needles.—The improvement in the characteristics of steel is making possible an eminently justifiable trend toward small needles in every form of manipulation. Thus the gauges may be revised downward, the ordinary spinal needle being now 20 gauge, which is, however little flexible for the inexperienced, and the 16-gauge blood-drawing needle being used only occasionally. The 26-gauge hypodermic needle is now preferred in my practice to the 20-gauge intravenous needle and the 22-gauge needle is quite satisfactory.

For intramuscular work, using the aspiration test 20- to 22-gauge needles, 1½, 2, and 2½ inches from the tip of the hub to the point are recommended according to the thickness of the buttock. In the huge buttocks of obese women, a 20-gauge spinal needle is sometimes invaluable.

Special Considerations Regarding the Spinal Needle.—The reduction of seepage from the meningeal puncture wound, has brought forth a number of modifications. The Hoyt needle encloses the inner shaft in an outer sleeve, the stylet fitting the inner shaft. The inner shaft is longer than the outer and when the outer or penetrating needle reaches the dura, the inner needle is advanced to puncture it. This device has been favorably reported as reducing the incidence of headache, but causes delay and tactile uncertainty in the inexperienced and on routine work. Tapering the point, as in some French types of needles, always involves the risk of fracture. The Pitkin point, a very flat bevel, is intended to leave a small "lid" of dura adherent to one marg

of the puncture hich acts as flap closure W prefer the Greene type of point which leaves a structurally simple and sound needle whose antileak qualities have been experimentally demonstrated.

Testing of Needles to Prevent Breaking in Use.—Figure 103 illustrates the method of testing the spinal needle with stylet removed

The hub is held firmly in the right hand and the shaft laid on the ball of the thumb, at the junction of shaft and hub. The index finger is then pressed down on the needle and bending stress sufficient to carry the shaft through an angle of 45 degrees is applied as the fingers are drawn from the hub to the point of the needle. W have never known needle which would stand this test to break in use, and it should be routinely applied once week during cleaning to all needles which are subject to heavy usage. The same test may be pplied t intramuscular needles The weak point of shorter needles is at the hub, and in the case of the Schreiber just pointward of the guard, so that the Schreiber should not be ground down too short to allow good safety margin outside the vein.

The lif of needle cannot well be measured in time, and depends much on the care which it receives. It is better t discard a spinal needle after fifty punctures than to wait until it breaks, either in testing or on the patient. N spinal needle which has been sharpened down so far that it does not leave 1-inch margin outside the skin when the dura is entered, can be regarded as entirely safe.

THE PREPARATION OF THE ARSENICALS

Remarks on Technical Systems.—The ensuing sections of this chapter outline essentially systems which have been found to work successfully in large numbers of cases and which are the products not only of thought applied to our individual methods but in comparison with the methods of others. On the other hand it is well realized that personal modifications very properly develop to fit special aptitudes and situations and that to talk of standardization to those who are already experts, is, of course, a work of supererogation

But system on service of any considerable size makes it possible to trace mistakes. If it is founded on sound principles, it fits the large majority of those who are called upon to use it If speed and technical accuracy are essential, it meets the need and spares the patient. It furnishes definite scheme of teaching and basis on which the beginner can align his own work I the instruction of medical students it is very helpful. N one should be asked t discard method which gives him completely satisfactory results, but the inexperienced can at least gain something by consideration of principles and fit their practice to them or the reverse, as best they can. Our system and equipment are offered only as one of many nd for what they are worth.

Preparation of the Arsenicals—Know the Ampules on Sight.—Every user of the arsenicals should familiarize himself with the color odor consistency and solubility of the preparations he expects to use. He should see the ampules in their original wrappings and should read every word of the labels. While he is familiarizing himself with the work, he should under no circumstances allow a nurse or assistant to open or prepare his ampules. To delegate any of these responsibilities to others, before he himself becomes so expert that he can recognize the drug and solution he is working with by instinct and on sight, is to take an unjustifiable risk for his patient.

Sterilization and Detection of Flaws in Ampules.—The ampule containing the drug should be immersed completely in 95 per cent alcohol (a denatured alcohol containing no metallic or methyl alcohol denaturing agents is allowable) It should be allowed to soak in alcohol for thirty minutes before use This will sterilize the surface will slightly moisten the contents, if there is a crack or perforation, and will reveal a very fine crack if the powder be shaken

around in the ampule before opening If there are any imperfections, the ampule should be discarded or returned to the manufacturer

The Ampule Label.—Removal of the pasted label on the ampule depends on the circumstances under which the drug is used. In large services manned by experienced operators who are perfectly familiar with the drugs, and in which fixed dosages are regularly employed, the labels should be removed by soaking in water or scraping before disinfection in alcohol, because of the slight possibility of glass defect beneath the label. The individual user less familiar with the drug, is wiser to keep the label intact and sterilize it with the ampule, far as possible, so that he may know at any and all times what he is dealing with by simply glancing at the label. Under such circumstances, he should handle the ampule with sterile forceps and piece of sterile gauze, after he is scrubbed up.

The ampule label carries the manufacturer control number of the drug and should be preserved either as matter of record or to trace complications and difficulties. It is rarely needed, but when actually needed is usually missing. It is our custom to record in a treatment book the lot number of each preparation used and t whom it as administered.

Preparation of Arsphenamine (606) for Administration.—Arsphenamine (606) requires neutralization before administration. An effort is being made to facilitate this by dispensing with the drug a ceresin or paraffin-coated vial containing the precise amount of sodium hydroxide of standard strength necessary to neutralize the dose of "606" which it accompanies. This device originated by Raiziss and employed by Cannon (1939) in his simplified technic for administering old arsphenamine, is a great saving and convenience and materially simplifies the most vexatious feature of the technic. Where this is not used, the following specifications for the sodium hydroxide solution must be heeded

Normal sodium hydroxide solution is employed in the neutralization of arsphenamine solutions in accordance with the standards of the United States Public Health Service, the concentration being determined by titration against normal hydrochloric acid solution. A normal NaOH solution is approximately 4 per cent, but if made up by weight, the absorption of water by the salt makes the molecular concentration very uncertain and exact quantitative neutralization is impossible. If it is impossible to secure titrated solution, 4 per cent solution may be used The NaOH must be chemically pure and the water used in making up the solution should be the same as that employed for arsphenamine administration. The older drop neutralization technics specify freshly prepared solution and 15 per cent concentration. In order to keep sodium hydroxide solution it is necessary to use glass-stoppered bottle coated with paraffin or ceresin as above described. In any case, it is not advisable to make up more than week supply of the solution at time, unless it can be kept in closed buret system. This protects it from absorption of moisture and carbon dioxide as well as from the glass. The solution is self-sterilizing. In the office, where only occasional injections are given, 4 per cent sodium hydroxide solution may be freshly prepared, boiled in large resistance glass test tube and used t once (drop method)

The Intravenous Administration of Arsphenamine (606)—Inasmuch as good deal of manipulation is involved, it is advisable for the operator to scrub up as for surgical procedures putting on sterile gown and dry sterile gloves. The mixing flasks are then rinsed with the specially prepared water at the temperature recommended by the manufacturer in the direction, accompanying the ampule. In present practice, water at room temperature is preferred to hot ater If the flasks are capped so that their edges are sterile which is the preferable method, direct pouring from vessel to vessel is possible The filter cotton is placed in the funnel and rinsed with sudden douche of specially prepared water and the cylindrical container (Fig 110) or buret is rinsed, filled with sufficient ater t wash out the rubber tubing thoroughly and assure its being filled ith ater (raise and lower repeatedly nd squeeze to be sure all air bubbles are dislodged). The ampule is then removed from the alcohol, thoroughly dried th sterile gauze, special attention being given to the neck, filed and the tip struck off It is not desirable to have too large an opening, hich will dump the drug on to the bottom of the flask to form difficultly soluble bolus. Instead, the drug should be sprinkled around the sides and bottom of the wet flask. Ten cc. of specially prepared water per decigram is then poured into the flask and by rotary swinging motion, the arsphenamine rapidly passes int solution ithout shaking or aeration.

As soon as the arsphenamine is completely dissolved (and there should be no residue), if the solution is perfectly clear and of normal odor (to be learned only by experience), neutralization may be begun. Solutions which have a very pungent and penetrating smell or which are even slightly cloudy or opalescent are unsaf and should not be tinkered with but discarded.

Neutralization Technic.—The neutralization of the arsphenamine solution may be accomplished by three accepted technics which are roughly or exactly quantitative, as distinguished from the older qualitative technics. Neutralization to form the disodium salt with an untitrated sodium hydroxide solution may be performed by counting the number of drops or droppers full of the solution required completely to precipitate, and completely to redissolve the yellowish-white arsphenamine base. One fifth t one fourth more is then added and we have even used little as one sixth, with satisfaction. While this procedure does not give even an approximation to quantitative production of the disodium salt, it gives very satisfactory mixture of the mono- and disodium salts for ordinary use. The method, however is difficult and unsafe for the inexperienced and properly displaced by exact quantitative neutralization with titrated solutions

Quantitative neutralization by the buret method may be used with either a titrated normal or an untitrated (4 per cent by weight) solution of sodium hydroxide. T produce the disodium salt with titrated solution of NaOH, add an amount representing 0.85 cc. for each decigram of the arsphenamine used, regardless of the amount of water in which the arsphenamine is dissolved. Thus, for 0.3 Gm. arsphenamine, 2.55 cc. of NaOH solution is added for 0.4 Gm., 3.4 cc.; for 1 Gm 8.5 cc. and so forth. If slightly less alkaline mixture of mono- and disodium salts is desired, 0.75 t 0.8 cc. normal NaOH solution per decigram is added. The calculated amount of the NaOH solution should be added all t once. To produce the disodium salt with roughly prepared 4 per cent solution but one in reality of uncertain strength, add small amounts from the buret until the visual end-point is reached, using essentially the same procedure as with the dropper technic.

The pH of the properly prepared arsphenamine solution varies from 9 to 10. The solution should be perfectly clear without trace of precipitate or cloudiness. On allowing solutions to stand, after the older methods of neutralization, they would occasionally "fix back" to slight opalescence, indicating the presence of the base, which could be cleared up by adding drop or two of the alkali, but with quantitative neutralization, no such phenomenon should occur If it does, it indicates something seriously wrong with the drug or technic, and the whole situation should be gone over and the solution discarded. Look especially to the strength and purity of the NaOH.

Inexperienced operators should test their solutions with litmus, transferring drop on sterile glass rod to piece of litmus paper (do not touch rod to paper) in order to obtain visual evidence of the series of reactions through which the preparation passes. On the other hand, it cannot be too strongly stated that only the dangerously ignorant or foolhardy will attempt to "tinker with an incorrect arsphenamine solution or to administer solution which has not behaved normally The addition of hydrochloric cid to solution which is supposedly overalkalinized cannot be too vigorously condemned. Only solution hich the operator believes to be prepared *secundum artem* up t the moment of injection, should go into patient vein.

Reduction of Toxicity by Standing.—When the solution of arsphenamine has been completely alkalinized, it should be set aside from thirty minutes to an hour the top of the mixing flask or the container being covered with sterile beaker or watch glass.

The Container.—The finished arsphenamine solution may be poured at once into the container or allowed to stand before pouring The cotton-containing funnel is used for filtration. After the solution is poured in, specially prepared water is poured through the cotton to wash the filter and to make the solution up t the proper concentration of 20 t 25 cc. per decigram of the drug In clinic practice, volumes of solution as high as 5 to 10 Gm. of the drug may be made up at time (5 Gm. t the liter) and poured through the filter as needed. The tip of the rubber tube, with its adapter should be kept sterile.

Wastage occurs in all manipulations except neutralization and in practice is provided for by allowing an excess of one tenth in mixing over calculated needs. It is better to have little left over than to skimp the doses.

Preparation of Neoarsphenamine for Intravenous Injection.—Neoarsphenamine should be kept in a cool, dark place, preferably a refrigerator Only one dose should according to standard instructions, be prepared at a time. Only the preparation for the syringe technic is described. The equipment consists of a supply of the freshly prepared water in flask or ampule two

medicine glasses (Fig 113) and the syringe shown in Fig 112. Neoarsphenamine ampules are rarely large enough to mix the drug in ampule and in safe

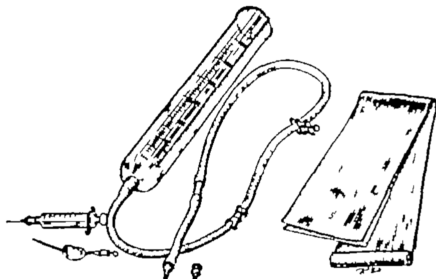

Fig. 110.—Single buret (300 cc.) for gravity administration of arsphenamine, fitted with tubing, pinch-cock, screw clamp, glass tell-tale, and adapter Syringe for local anesthetic, Schreiber needle, and band tourniquet.

concentration In all handling of syringes and glass, whether with or without sterile gloves, the operator should not touch the inside of the glasses or that

Fig. 111 —Convenient form of spring clamp, made of nickel-plated brass which can be sterilized by boiling.

part of the piston of the syringe which enters the barrel. Precautions with reference to the ampule and inspection of the drug should be strictly observed

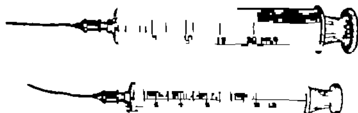

Fig. 112.—Types of syringe used in intravenous neoarsphenamine and intravenous mapharsen administration. Note that in attaching the needle the bevel should be toward the graduations and the needle introduced bevel up. The curved needle can be bent t adapt it to angular surfaces as about the jugular and cephalic veins. The guard is omitted in our recent work, the syringe barrel being controlled by the right hand and the piston by two fingers of the left.

After flushing the lip of the flask, specially prepared water at room tempera ture is poured into one of the glasses or the water from an ampule poured into

it. The ampule of the drug is opened after careful wiping of the neck, and the dry powder poured into the other glass. If preferred the requisite amount of

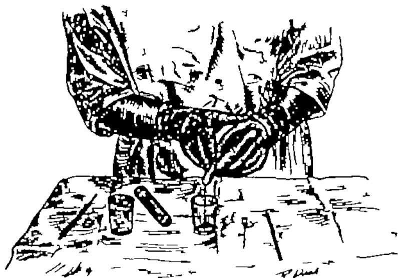

Fig 113.—Equipment required for the administration of neoarsphenamine. The specially prepared distilled water is in the medicine glass to the left, and the drug is prepared one dose at a time

water (10 cc.) may be aspirated by the syringe after rinsing, and discharged into the second glass, the neoarsphenamine powder being poured upon the surface of the water But the pouring of the water on the drug is preferred for

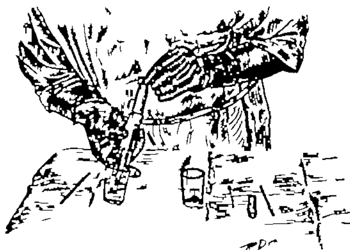

Fig 114.—Preparation of neoarsphenamine for intravenous use. The powder is in the right-hand medicine glass, and the required amount of water is poured upon it from the syringe

the powder then remains in the bottom of the glass instead of floating about the syringe By slow and careful aspiration and ejection of the water without spurting or bubbling the neoarsphenamine is completely dissolved (Fig 115)

The *incorrect* method of dissolving neoarsphenamine by holding the syringe with water at a distance and squirting it to produce a froth, thoroughly aerates

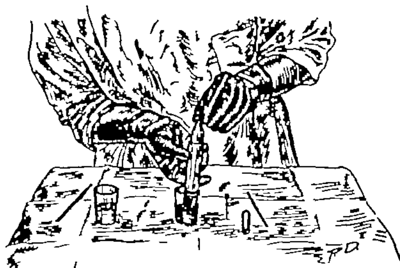

Fig 115.—Proper method of hastening the solution of the neoarsphenamine, by gently aspirating and expelling water with the nozzle of the syringe always below the surface to avoid bubbling.

and toxifies the drug, as shown in Fig 116 It is always the mark of a greenhorn to squirt neo solution or solvent. When the drug is completely dissolved the

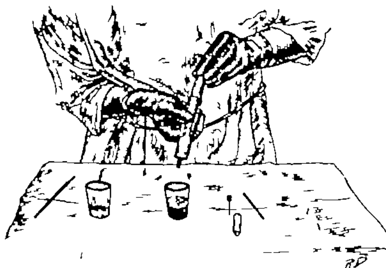

Fig 116.—Neoarsphenamine should not be squirted since aeration increases toxicity Mapharsen should be squirted since aeration decreases its toxicity

solution is inspected to be sure that there is no residue. Rapidity of solution and absence of residue are the most important protections against the mistake of injecting arsphenamine instead of neoarsphenamine a blunder unfortu

nately made in the best clinics, occasionally The glass should be held to the light for certainty in this matter A properly made neoarsphenamine should go into solution within two minutes, although the U.S.P.H.S. standards allow as much as twenty minutes. If solution is incomplete the drug should be discarded. Not more than twenty minutes should ever elapse between solution and administration, and it is preferable to give the injection at once. The medicine glass should be thoroughly rinsed after the mixing is completed and none of the drug held over for more than ten minutes to the next mixing If a second ampule must be mixed to complete the dose from the remnant of the first, a third medicine glass should be used and the second solution judged on its own merits.

Filtration of neoarsphenamine solution is usually unnecessary If desired, aspiration may be made through a small needle to exclude gross particles.

After the solution has been drawn into the syringe through the needle, all the air is expelled as the syringe is held vertical. Intravenous injection is then carried out in accordance with the technic described on page 309

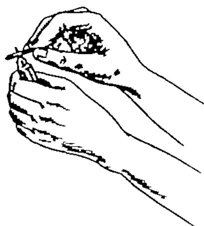

Fig. 117 —Ampule technic for certain arsphenamines. Opening the ampule (After Cazelman)

Preparation of Mapharsen Solution for Intravenous Injection.—*Single Dose Ampules* (A) Mapharsen solution may be prepared directly in the syringe if desired. Draw ten cc sterile distilled water into a syringe to which an intravenous needle (preferably 21 gauge) is attached. Expel approximately 1½ cc. of this water into the single dose mapharsen ampule, then draw the solution back into the syringe. Repeat this several times or until the mapharsen is completely dissolved Finally to complete mixing and to remove free carbon dioxide draw air through the solution in the syringe several times. The solution is then ready for injection

(B) Mapharsen solution may be prepared by adding the contents of a single dose ampule to 10 cc. of sterile distilled water in a sterile glass container stirring vigorously until completely dissolved The solution may be freely aerated by drawing into and expelling from a syringe several times.

Hospital Size (10-dose) Ampules Dissolve the contents of a 10-dose ampule (0 4 gm. or 0 6 gm) of mapharsen in 100 cc. of sterile water Stir vigorously and fill syringe with amount of solution necessary to contain the required individual dosage Ten cc. will contain a full dose, five cc. a half dose etc.

Mapharsen or dichlorophenarsine hydrochloride solutions may be allowed

to stand for several hours exposed to air with no increase in toxicity or loss in efficacy

Silver Derivatives for Intravenous Injection.—Since there is decided difference between the composition of silver arsphenamine, sodium silver arsphenamine and neosilver arsphenamine

Fig. 118.—Injecting the solvent, thus dissolving the drug.

the instructions of the manufacturer should be followed. Salt solution, 0.4 to 0.8 per cent, must be added in various technics after dissolving the drug in cool water The solution should be of bright and sparkling brown color not turbid or muddy which indicates an oxidized drug.

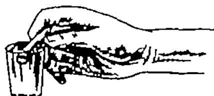

Fig. 119.—Allowing ampule to stand, with shaking (*not with neoarsphenamine*) to insure solution. Inspect for undissolved particles.

Ampule Technic for Intramuscular Administration of Sulpharsphenamine and Bismuth Arsphenamine Sulphonate.—The ampule of the drug is inspected and prepared as in the case of other arsphenamines. The only equipment

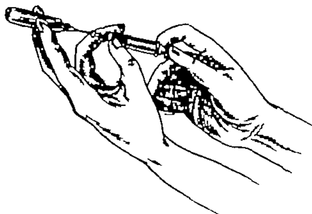

Fig. 120.—Refilling the syringe for injection after solution. Change needle before injecting

required is a 2 cc. all-glass Luer hypodermic syringe graduated in cubic centimeters, needles for intramuscular use, and a sterile medicine glass containing the specially prepared distilled water One and one half to 2 cc of the water in accordance with the manufacturer's directions, is aspirated through the

needle into the syringe and then injected into the ampule containing the drug The technic of handling ampule and syringe is shown in Figs. 117–120 The drug can be aspirated back and forth a few times and agitated without fear of aeration and when completely dissolved is drawn up into the syringe *There must be no undissolved particles, and a fresh, dry needle should be* used in injecting the drug—not the needle used in preparing the solution. None of the unused solution can be held over for a subsequent injection Maximum doses are often wisely divided between the two buttocks.

If a local anesthetic, such as butyn, has not been added to the ampuled water employed in preparing the drug for injection two to four drops of a 4 per cent butyn solution may be added after the drug has been dissolved in the ampule

THE TECHNIC OF INTRAMUSCULAR INJECTION

Importance.—The importance of an exact technic in intramuscular injection soon becomes evident on questioning patients who have given up treatment prematurely An unsatisfactory technic of intramuscular injection is quite largely responsible for the practitioner's difficulties in carrying through a modern treatment regimen, and with other causes, ranks, according to the observations of Pugh *et al* as one of the weak points of modern clinic methods. The older suggestions as to rational procedure were largely empirical and only recently in this country by Zwick and Batson and by Shaffer has a genuine effort been made to determine the rationale for the procedure. The technic here offered was originally designated as epifascial in accordance with the terminology of Wechselmann but it has since been shown *by Shaffer that it is in* reality intramuscular and that the term epifascial should be discarded

Intramuscular injection is, in our experience best performed by women technicians and nurses who are lighter of hand and more dexterous than men. Large men are particularly apt to be heavy-handed and ungentle and patients frequently protest their ministrations in intramuscular injections Deftness of touch and speed of action are both essential.

Site of Injection.—Shaffer in particular showed that the site of injection should bear intelligent relation to the anatomy of the underlying parts that only in one region of the buttock, for example was a minimal reaction to be expected—namely the upper outer quadrant. He showed that the drug suspension should be delivered deep into the body of the muscle that it spreads itself longitudinally along the fascial bundles (in the case of the gluteus maximus diagonally across the buttock from within outward and downward) and that the leaking-back of the emulsion along the needle track could be reduced by keeping the needle in place for at least a minute following the injection. The rate of distribution depends somewhat upon the medium, oily suspension being slower than aqueous. Pain down the leg following injection in the buttock, is, in Shaffer's opinion, due to irritation and injury of the lesser rather than the greater sciatic, as has previously been supposed

The buttock should always be palpated for old infiltrations and tender spots before an intramuscular injection is given and it is well to ask the patient if he has ever had sciatica or pain down the leg before giving the first injection. The first 3 or 4 injections of any intramuscular preparation are almost invariably painful and several small doses are sometimes recommended at one-day intervals before a regular course of intramuscular injections is put

under way in order to "harden or toughen the buttock. The initial discomfort soon disappears

The site of injection in intramuscular work should be sterilized either with iodine, which, however may set up irritation and which corrodes and pits needles or preferably by vigorous scrubbing with alcohol until the skin is red.

Two additional points have had strong emphasis from recent investigations an active muscle is a much better site for intramuscular injection from the standpoint of absorption and general quick recovery than an inactive muscle, and massage following injection is one of the most important preventives of local reaction and accelerators of absorption available

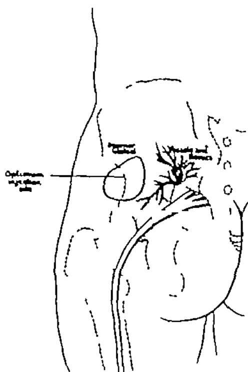

Fig. 121 —(After Shaffer.)

Other sites than the gluteus maximus may be employed for intramuscular injection, including the infraspinatus muscle and the deltoid, but these are relatively unsatisfactory both on the score of slow absorption and materially increased pain from the majority of modern antisyphilitic medicaments. Deep subcutaneous injection has been advocated for sulpharsphenamine (subscapular by Casselman, deep subcutaneous by Arwyl-Davies)

Procedure —The technic here described applies particularly to the use of the buttocks In Fig 121 are shown the anatomical structures involved in their relation to the surface outline, and from this it becomes apparent that injections delivered near but not at the inner angle of the upper outer quadrant, the needle being introduced vertically have the best outlook for uneventful absorption If delivered too far toward the crest of the ilium, the needle may strike bone or obstinate pain may result, and if too close to the central point of the quadrant, one or both sciatic nerves may be involved. The upper inner

quadrant is open to the same objection and the patient sits on both lower quadrants, thus materially increasing his annoyance and discomfort.

Instruments.—These have been described on page 297 (Figs. 112, 122) The caliber of needle will depend somewhat on the thickness of the suspension, 22-gauge needles being used for aqueous solutions, 21-gauge for oil suspensions.

Sterilization.—Needles and syringes are preferably sterilized by boiling for ten minutes, though pure alcohol may be used, if necessary

Preparation of Emulsions.—Suspensions of insoluble drugs require most thorough and systematic shaking whether in ampule or in bottles. Preliminary warming is useful in most preparations and actual heating necessary in some the manufacturer s directions to be followed in this matter Cole, and his co-workers have shown that under routine clinical conditions the amount of drug in the suspension may vary greatly between the top and bottom of a bottle, even after supposedly proper shaking A useful clinical test is to turn the container upside down to see if any adheres to the bottom If it does shaking has been insufficient.

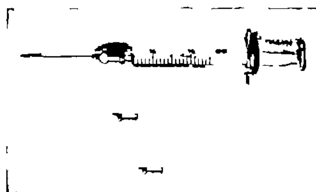

Fig. 122.—All-glass Luer syringe, with the various sizes of needles used for intramuscular injection.

Beerman adapted the Kahn shaker in common use for the laboratory test to the shaking of bottles of heavy suspension. The container should be repeatedly shaken at intervals for periods of two or three minutes throughout forenoon work and suspensions should not be allowed to remain in the syringes long before they are injected.

The Needle.—In general it is desirable to employ a clean dry needle for the introduction of a suspension and the question as to whether or not the needle should contain the emulsion becomes academic when the aspiration test presently described is used. The external surface of the needle, however should not contain the slightest traces of the drug to be injected, for this is a frequent source of skin infiltration and discomfort. It is desirable also to empty the needle into the tissue before withdrawal by carrying an air bubble between suspension and piston which can be injected through the needle into the muscle, thus clearing it completely without the slightest ill effect.

Posture of Patient.—Intramuscular injections may be given with the patient standing or lying face down, preferably the latter A sitting posture is described by Cornbleet (1939) self-administration by Waugh and Heering Women should remove their corsets, for the snap of a pulled-back girdle, striking the hand, has, in our experience broken a needle. The patient should relax by turning the head away from the operator and the posture of "toeing-in to

relax the gluteus maximus is shown by contrast with the effect of "toeing-out in Fig 123 It is advisable always to warn the patient, for a sudden jerk or twitch may break a needle. When warned he may be instructed to draw a deep breath. Allowing the arms to hang over the sides of the table further induces relaxation and prevents stiffening of the buttocks

Needle Entry—The position of syringe and needle as held by the right hand is shown in Fig. 125 The left hand is placed flat on the buttock as shown in Fig 124 and the skin and superficial tissues then drawn downward by traction. On release these tissues provide the valve that prevents leakage along the needle track Two motions are possible for the introduction of the needle (Fig 125) one a dagger-like stab whose quickness makes it relatively painless but which has the disadvantage of lack of control and increased danger of

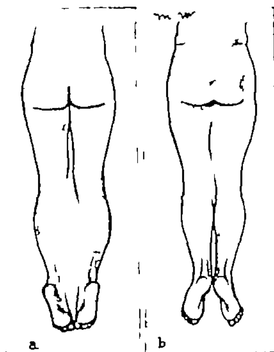

Fig. 123—a, "Toed-in to show the relaxation of the buttock, b, "Toed-out with the dimpling of the buttock indicative of a tense musculature

breakage the other a resting of the side of the hand upon the skin to steady it, a placing of the needle point almost in contact with the surface, and then, by a quick twist of the wrist, a passing of the needle through the skin. This with a little practice can be done very rapidly and the remainder of the entry is painless and can be made as a separate movement. The needle should not be introduced to the hub (the illustrations shown are in error on this point) but should have a margin of at least a half inch to prevent the complete loss of the needle in case of breakage

Aspiration Test to Detect Deep Bleeding—This test is of the greatest importance, especially with insoluble suspensions Its purpose is to detect the entry of a deep blood vessel, for there are a number of large ones in the buttocks with the consequent dangers of delivering the injection mass into the

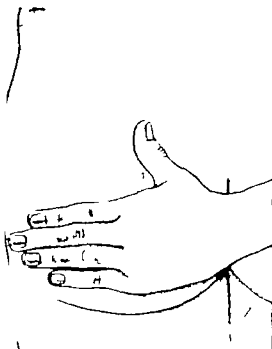

Fig. 184 —Left hand drawing down the buttock.

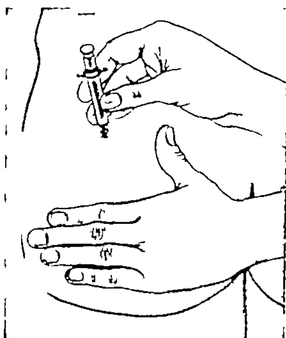

Fig. 185 —Introduction of the needle

blood stream. After the needle has been entered with the right hand, syringe attached (it is not necessary to remove the syringe or to introduce the needle

separately) the left hand releases the drawn-down tissues of the buttock and the right, after accommodating to the new position of the syringe and needle steadies the syringe while the left hand is used to pull upward on the piston, aspirating for a period of not less than five and preferably ten seconds (Fig 128) *No other method seems quite so effective in disclosing leakage of blood in the neighborhood of the needle point.* If the slightest trace of discoloration appears in the suspension within the syringe, the needle is withdrawn and a new entry made 1 or 2 cm distant from the first one At times an operator may enter an unsuspected deep abscess, securing pus or a grumous fluid instead of blood.

Injection.—The introduction of the suspension should not be forced and t should seem rather to flow in. Gradual withdrawal of the needle during in

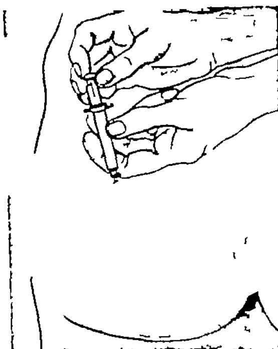

Fig. 128.—Aspiration to test for the presence of the needle in vein.

jection has been recommended but only in the case of larger volumes of solution Injection under pressure and withdrawal both carry the risk of leakage along the needle track with resulting nodular infiltrations of connective tissue and skin. These can be almost entirely avoided by the use of small enough needles and the quick upward push of the downward-drawn superficial tissues as part of the 'valve action secured by the left hand

Old fibrous buttocks, "*fesse en bois*," which have been the recipients of long series of intramuscular injections, sometimes positively refuse to be injected any further and either return the suspension into th needle or through the puncture wound on withdrawal.

Massage.—An extremely important tem following intramuscular injection is *adequate massage* (Fig 129) This point has been emphasized by Boyd and by Colonel Harrison It is well to massage the site of injection

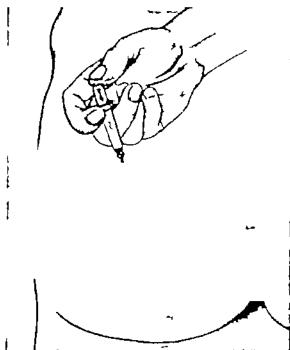

Fig. 127 —Injection the emulsion or solution should flow in freely and not have to be forced

Fig 128.—On release of the left hand the tissues of the buttock return to their normal position, producing valve action. The emulsion is spread out in the muscle tissue and leakage prevented by persistent massage ith cotton pledget. The massage may be prolonged to five minutes or more by the patient.

deeply and firmly though not roughly for at least one minute while the patient still lies on the table, and Colonel Harrison has had very satisfactory results from having the patient massage himself still longer with the use of a species of flat glass pestle for which the doubled fist is only a fair substitute Time spent on careful massage materially favors the absorption of the drug and reduces the incidence of post-injection discomfort.

The prevention and treatment of complications of intramuscular injection are considered in the next chapter (p 305)

THE TECHNIC OF INTRAVENOUS INJECTION

Unlike golf the intravenous injection has no official stance, no professionally authoritative technic of drive and putt. An average degree of proficiency in intravenous work can be acquired with reasonable rapidity pro-

Fig. 109 —Plaster manikin of an arm with venous circulation of rubber tubing, colored water for blood, rubber dam for skin, and yellow solution for injection used to train students in intravenous injection technic.

vided some thought is given to a definite reasoned-out system of movements. That this is seldom undertaken is suggested by the really surprising posturings one occasionally observes through the glass windows of operating and treatment rooms. For purposes of instruction, one of us (J H. S) attempted to detail in 1917 the steps of a technic of intravenous injection which had gradu

ally evolved on his service from a combination of reasoned considerations and the good points of several methods which he had observed and used This technic, assisted by manikins (Fig 129) has since been employed successfully on our University service for student instruction (Stokes and Beerman) Provided the series of steps here described is rigorously followed and exactly repeated the desired result, a successful venipuncture can be obtained in the overwhelming majority of cases The essential items in the correct technical approach involve

1 A satisfactory choice of needle
2 The position of the arm

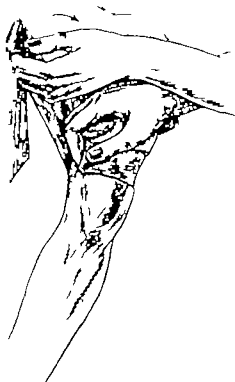

Fig 130.—Method of application of the band tourniquet to the left arm.

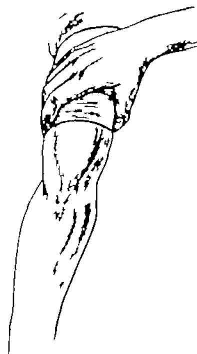

Fig 131 —The band tourniquet, in place, can be held by the patient or assistant, and released simply by loosening the grasp, without jerk or distortion of the veins.

3 A proper application of the tourniquet.
4 The identification and preparation of the vein.
5 The four-point technic of entry

The Needle —This has been discussed on page 288 Due allowance, of course, must be made for the taste of the individual operator in selection. In general, however it may be said that most needles for intravenous work are larger than necessary and cause needless pain and leakage.

The Position of the Arm and Operator —The arm should be extended at right angles to the body with the patient lying down. A sitting position is preferred by some operators, but in each case it is essential that the arm rest

on a slightly slanting support at desk level so adjusted that the elbow is really in a state of forced extension. Much trouble arises from failure to extend the arm completely. It is wisest to expose the entire arm and neck without constriction, the arm being drawn from the sleeve rather than the sleeve being rolled up.

The operator should address himself directly to the arm, working with his line of sight along the course of the vein which he expects to enter and not at even the slightest angle to it. Offside entry is a frequent source of difficulty.

The Tourniquet.—A broad rubber band, such as an Esmarch bandage, a piece 30 inches in length by 2 or 3 inches in width, is the most satisfactory tourniquet, though pieces of rubber tubing clamped by hemostats are frequently employed. When the band tourniquet is used, as in Figs. 150, 151, the folded end may be tucked toward the outer side of the arm and the encircling band drawn over it under tension, thus satisfactorily compressing the arm and catching the end as the band is brought across to the median side. Assistant or patient can then easily control the tourniquet by pressure with the thumb and index finger on opposite sides of the arm, and release without twisting or jar can be secured simply by letting go and lifting the part of the tourniquet covering the anterior surface of the arm. In applying a tourniquet on muscular arms, the compression should not be too great, lest the arterial supply also be partially cut off. The use of the blood-pressure cuff controlled by the patient, also makes a satisfactory but rather more troublesome tourniquet.

Identification and Preparation of the Vein.—The arm should always be inspected before and again after application of the tourniquet. Injection of arsenicals into varicose veins of the leg is deprecated as unnecessary and inadvisable. Palpation may be of more assistance in deciding the vein to use than inspection. Light downward pressure and cross-stroking with the ball of the finger will identify even a very whitewalled or deepseated vein. The poorest types of veins are the pale superficial tracery, easily visible and distensible, but very thin walled; the corded, tortuous or stiff walled veins poorly fixed in a lax, atrophic skin, that recoil and wriggle up the arm before the needle; and outright invisible veins under a deep panniculus. Such veins, inaccessible elsewhere, sometimes appear for 2 or 3 cm. of their length, just at the elbow bend, as a pale blue spot, invisible by very yellow or otherwise poor light but palpable with a "distended tube" feel on downward pressure with a sensitive finger. A skilled operator will often manage a difficult case much more by palpation of such veins than by sight. A watch should be kept for previous thrombosis, which can be recognized because the vein, paler than normal, slips sharply or snaps under the finger as it is drawn across it and yields a definite cordlike feel. Where one arm fails to show a satisfactory vein on first inspection, the other arm should be investigated. Where possible, arms should be used alternately for intravenous work. The point for entering a vein should be as near the operator and as far from the heart as possible, so that if a second puncture becomes necessary, it may be made above the first to avoid leakage of the injected liquid through the original puncture wound.

Poor Veins.—Poorly developed or difficult veins may often be given a satisfactory degree of dilatation by the following devices: (1) Several sharp slaps with the flat of the hand at the site to be injected; (2) by distending the arm vessels by soaking in hot water or applying hot compresses; (3) by the systematic use of daily arm gymnastics; (4) by mopping the surface of the

vein with xylene after the sterilization (5) by the routine "pumping up" of the vein by vigorous opening and clenching of the fist followed by clenching during the period of application of the tourniquet (6) by increasing the slant of the arm.

Toughness of the skin, which makes the entry jerky and tends to transfix the vessel, is chiefly a factor in veins at the wrist and at the condyle of the elbow where the resistance encountered is much greater than at the flexure. Veins on the back of the hand occasionally tempt the operator to his later regret, for the toughness and mobility of the skin the shallowness of the veins, and the delicacy of the walls, all tend to a poor technical result.

Preparation of the Injection Site.—Two per cent iodine in ether or tincture of iodine may be employed for sterilizing especially on dirty arms, but vigorous scrubbing with 70 per cent alcohol as in intramuscular injection until the skin is red serves both to dilate the vein and to provide adequate surface sterilization. Iodine must be avoided in highly susceptible skins or in patients threatened with dermatitis.

Local Anesthesia.—One of the seemingly trivial elements in smooth-running technic is the confidence and cooperation of the patient. Operating under general anesthetic, one seldom realizes the psychic effect on an operator of a nervous or distrustful patient. Panic may seize even the fairly experienced, if the goal is not reached on the first attempt The tense attitude, the arm that bends instead of straightening at the slightest needle-prick, the shrinking way the sounds of remonstrance and disapproval from the patient, are only too efficient in bringing beads of sweat to the operator brow and in damaging the fine movements of the hands on which his success depends. T stop to cool off may only make matters worse, and to fail entirely may damage his nerve in subsequent work as well as that of his patient, more than is realized. For these reasons we have insisted on local anesthesia for years in the use of all needles under 20-gauge, with the most satisfactory results. The simple injection of 1 drop of 4 per cent sterile novocaine solution into the skin with 26-gauge needle forming wheal above the vein at the point of entry transforms intravenous procedure from an affair of haphazard hasty stabs into carefully considered and leisurely maneuver Patients repeatedly attest their preference, and the novocaine solution acts almost instantly so that there is no delay involved in its use. Care must be taken t raise wheal, not to inject into the vein wall or lumen.

The Four-point Entry —Whether an unattached needle or a needle attached to a syringe is employed the four steps for entering a vein are the same.

1 The first step consists in the fixation of the vein with the left hand (Fig 152) This should become absolutely automatic. It is accomplished by drawing downward the skin and tissues of the forearm by the flats of the fingers of the left hand held palm down. Without this step the vein creeps upward with the needle and a miss is very likely to occur

2. In the second step, the needle, whether guided by the fingers or the syringe is entered on the flat in the direction of the long axis of the vein In order to keep the needle as flat as possible, some operators prefer the eccentric syringe nozzle Colonel Harrison advises also that the fingers hold the syringe from above downward, the tips not passing the median plane of the syringe so as to permit it to be laid flat against the arm. We believe that in order to avoid a jerky entry which may traumatize the vein unnecessarily and to make the syringe controllable by the broader bearing surface, the second, third fourth and fifth fingers of the right hand should rest firmly upon the forearm of the patient at the tips, and the movement in introducing the point be thus controlled (Fig 152) In using the Schreiber needle only the fourth and fifth fingers rest on the arm of the patient, the first and second being used with the thumb much as one advances and withdraws the point of a pen in-

stead of using the coarser movements of the forearm. With the bevel of the needle uppermost and with slight downward and forward pressure the point is pushed through the skin but in the first movement is not permitted to enter the vein. This completes the second step (Fig 132)

3 The third step in the four-point entry consists in the puncture of the upper surface of the vein wall. With the point of the needle just visible as a slight elevation under the skin, advance the needle approximately ½ to 1 cm.

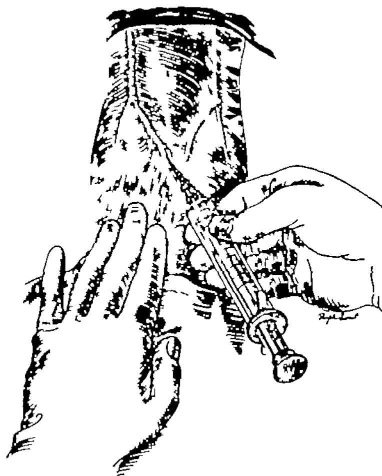

Fig. 132.—Syringe technic First motion, entering the skin, showing the tension exerted by the left hand to fix the vein and the pressure with the right for the purpose of steadying the syringe The needle point is visible under the skin, directly over the vein

so that it is visible as a ridge above the upper surface of the vein wall (Fig 133) Then very slightly raise the butt of the needle or the syringe coincidently with downward pressure of the point upon the roof of the vein. A slight advance of a properly sharpened needle then punctures the vein wall, and the moment this occurs the syringe or needle butt is again dropped toward the forearm flattening the needle out along the long axis of the vein, to prevent puncturing the far side of the vessel. The needle is then pushed up the vein for a distance of approximately 1 cm in order to avoid any possibility of leak

age under the bevel and to avoid discharging an irritant too close to the point of trauma

4 The fourth step is the demonstration of the fact that the needle is completely within the lumen of the vein and entirely free It consists in releasing

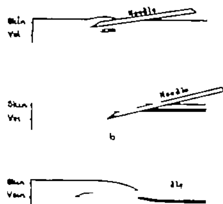

Fig. 133.—Sagittal sections showing the successive positions of the needle in the technic illustrated in Figs. 129–130. *a*, Entering the skin above the vein *b*, angle for entering the vein *c*, advancing the needle after entering.

the tension of the left hand on the forearm of the patient, and while still holding the needle or syringe in position by the right hand resting on the skin of the patient s arm in demonstrating the free flow of blood by pulling backward on the piston of the syringe or witnessing the gush of blood from the hub of

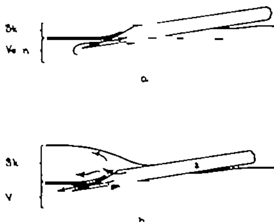

Fig. 134.—Illustrating the effect of partial puncture of vein, with long-beveled needle *a*. Return of blood has been secured without completely entering the vein *b*, infiltration of the subcutaneous tissue even after return of blood has been secured, soon injection is begun

the unattached needle where such is used (Fig 135) The characteristic spurt of the stream of blood across the fluid in the syringe is an absolutely essential concluding test of the correctness of the entry and must always be made before any attempt to inject the syringe contents or other medication is begun Even with a 26-gauge hypodermic needle, it is possible by pulling backward

on the syringe piston to secure a completely satisfactory return of blood, though in smaller amount, demonstrating the freedom of the point in the lumen of the vessel.

Procedure if Free Return of Blood Is Not Obtained.—If after introduction of the needle a free flow of blood cannot be obtained, the following pro-

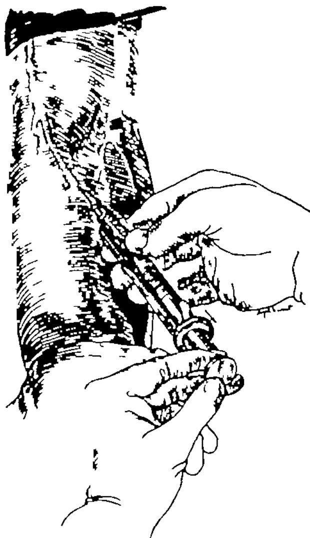

Fig. 185.—Syringe technic. Needle has been advanced, and return flow tested by pulling on piston. A stream of blood should shoot across the fluid if proper entry has been made. The right hand maintains its pressure.

cedures may be tried successively to ascertain the difficulty (1) The patency of the needle should have been investigated before injection by drawing freshly distilled water through it from a small sterile tumbler of water kept for this purpose. In the syringe technic air may be aspirated through the needle into the syringe and again expelled before the injection is given (2) depress the

point of the needle within the vein without advancing: the bevel may be shut off against the top of the vein (3) feel for the needle point with the free hand if it is still above the vein and has not entered the wall, it can be easily felt (4) *the syringe piston may stick and may be loosened by twisting in the barrel* and pulling back (5) transfixing of the needle point on the opposite side of the vein provided the vein has not been completely transfixed, can be remedied by slowly lifting up the needle point while the needle is withdrawn a *short distance it will come away with a quick snap if it is simply caught in*

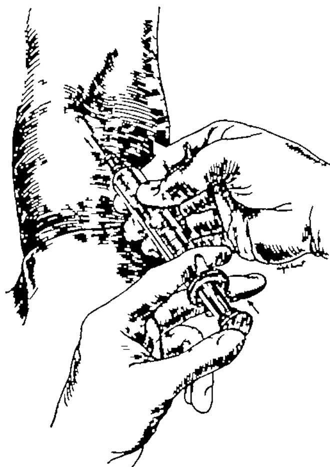

Fig. 126.—Syringe technic. Injection. The guard we have later found may be discarded and the piston controlled better by the thumb and two fingers of the left hand, since no force should be used.

the opposite wall (6) the needle may then be quickly advanced with the point *raised as high as possible, flattening the needle or syringe down to the* surface of the arm as much as possible (7) if the above measures fail the needle may be withdrawn until the point is just short of the skin puncture and another advance made under guidance of the palpating fingers. If this procedure fails twice, the needle should be withdrawn and retested for patency and the point carefully examined while this is being done elevation of the arm with pressure over the vein by a cotton pledget may make it possible to

use the same vein again (8) if leakage of blood into the subcutaneous tissue occurs during venipuncture begin over at another point never attempt to inject through a hematoma (9) never proceed to inject until certain that the needle is in the vein to inject a little and ask the patient if it hurts is evidence of lack of skill (10) one skin puncture may be used for several attempts and every effort should be made to make this one suffice (11) cutting down on the vein is absolutely inexcusable in these days and patients whose veins seem so inaccessible as to suggest the need for such a measure should be sent to an expert (12) make no comments audible to the patient regarding the condition of your needle.

Technic in Children.—The development of satisfactory intramuscular medication has made intravenous injection in infants less important, but it may occasionally be required. If necessary in small child, one or two skilled and determined assistants are usually necessary The child must be wrapped in triangular blanket similar t an intubation blanket, which completely restrains and immobilizes hands and feet. The child is then placed at full length on the table with the head turned t one side and firmly held. The crying of the child will usually distend the jugular vein and an entry can easily be made ith small very sharp steel hypodermic needle attached to 5 or 10 cc. syringe. Larger syringes are too hard t control. If head vein is used, such as the anterior auricular an all-glass hypodermic syringe may be employed Injection into the superior longitudinal sinus is mentioned only to be condemned, for serious reactions have occurred.

Older children, if visible arm veins appear may receive neoarsphenamine t the start with syringe and 26-gauge hypodermic needle until the child' confidence is gained. If arsphenamine (606) is to be used, the ordinary 20-gauge needle may be introduced by the syringe technic the syringe detached and the adapter on the container tubing inserted, if the dose is too large to use 20 cc. syringe. The 20-gauge needle should not be used without local anesthesia on child' arm, for once the confidence of a husky child is lost. battle royal usually ends in an infiltrated arm and the defeat of the operator Parents should not, in general, be admitted to the treatment room with their children. The repeated occurrence of uproar from children under treatment is evidence that the staff is working below par

Rate of Injection in Intravenous Technic.—This is controlled in accordance with the methods and according to the standards outlined on page 260 In general arsenicals should be administered intravenously at a slow rate, but mapharsen produces less trouble when the rate of administration is rapid.

TECHNIC OF INTRAVENOUS DRIP

The following description is abstracted from the account by Leifer (1940) given at the conference on massive arsenotherapy in early syphilis by the continuous intravenous drip method in behalf of the Committee on Massive Drip Intravenous Therapy See also Treatment of Early Syphilis, Chapter XIV

The apparatus employed in the intravenous drip is packed and autoclaved in special container with slot containing perforations hich is open while in the autoclave and closed at all other times to prevent contamination. Each set consists of gravity flask and two lengths of transparent rubber tubing connected by Murphy drip. The longer tubing is attached to the gravity flask; the shorter to an adapter which fits standard 20-gauge 1.5 inch needle. The drugs are dissolved in solution of triple distilled water containing 5 per cent dextrose The content of an ampule containing 60 mg. of mapharsen is dissolved in 600 cc. of the diluent (Vacoliter equipment may be used). Four doses of the drug in the diluent are given without intermission each day so that each patient receives 240 mg. of mapharsen in 2400 cc of 5 per cent dextrose solution which contains 120 grams of the sugar The rate of flow is approximately 6 cc. minute. Ordinarily the drip is set up about 8 m and the full dose has been injected by the end of ten to twelve hours. At the end of this period the needle is withdra n, treatment being discontinued during the night but resumed the next morning The procedure is carried out daily for five con-

secutive days until total of 1200 mg of the drug has been administered in 12,000 cc. of diluent containing 600 Gm. of dextrose. The total arsenic content is approximately 360 mg.

The choice of the vein is an important consideration. The elected site for the insertion of the needle has been a vein in the forearm between the elbow and wrist. This permits free movement of the elbow and no splint is required. The patient may assist in feeding and in nursing procedures such as the use of the bed-pan. There is less danger of dislodging the needle from this site than at the bend of the elbow where motion occurs. It is desirable to insert the full length of the needle up t the hub for firmer anchorage. The right and the left arm are used alternately for the injection procedure. Usually vein can be employed again after rest of twenty-four hours. Fresh solution is prepared for each patient t the end of two to three hours, and the gravity flask refilled. Meals are served on the ordinary bed trays. Patients can feed themselves. They are also capable of handling the urinal, and may read, listen to the radio, or play cards during the day Disturbance by the use of the bed pan may be prevented by having the patient evacuat or have an enema during the evening when treatment has been discontinued. After discontinuance of therapy in the evening the patient may get out of bed. They suffer little or no discomfort and may register gain in weight.

TECHNIC OF SPINAL PUNCTURE (RACHIOCENTESIS)

The ill-performed spinal puncture plays directly into the hands of neurosyphilis first by providing a specimen unfitted for complete examination (blood cell contamination) and secondly by leading the patient to break treatment or refuse further spinal fluid control. Unfortunately the examination of the spinal fluid is a much less simple procedure technically than the mere drawing of blood for a serological test. Lumbar puncture the simplest of the methods employed for obtaining the fluid presents a considerable technical difficulty quite measurable discomfort for the patient in the form of possible reaction, and a distinct though slight element of risk of injury or even of loss of life It follows, therefore, that except under pressure of emergency it should not be attempted by the inexperienced or without proper control over the patient. To do the test in the office, with the patient sitting on a stool or table, is distinctly second-best procedure. In certain circumstances, however it is unavoidable and we have seen no striking disadvantages, if the patient is cooperative With sufficiently small needles, an uneventful puncture and the proper use of sedatives a satisfactory ambulatory technic has been developed.

Equipment for Spinal Puncture.—As in the intravenous technic, perfection in performance is facilitated by uniform and satisfactory surroundings and equipment. The test can be performed at the bedside by an operator of experience On the ordinary low bed the operator should sit on the floor so as to bring the site of puncture a little below the level of the eye Under operating room conditions, a rigid table of such a height as to bring the middle of the back to the level of the operator s chin when seated should be used. If the patient sits, which is advocated only in rare instances of obesity or other special conditions, the stool should be high and the site of puncture also at the level of the operator s chin.

Needles should be sterilized by boiling for ten minutes ith the stylets each rapped with its own needle in thin gauze Alcohol free from corrosives is to be aspirated or poured through the needle before boiling if oil has been used. Additional equipment as follows: (1) One all-glass syringe (2 cc.) and hypodermic needle (26-gauge) for local anesthesia. (2) Two t 4 per cent novocaine, sterilized by boiling. (3) Full-strength tincture of iodine or 2 per cent iodine in ether (4) Medicated alcohol (no corrosives) (5) Six inch gauze squares, sterile gauze sponges, sterile adhesive plaster

A good office kit includes

1 A 8 x 8-inch box containing:
  Three 5 cc sterile corked and labeled test tubes for collecting fluid.
  2 tubes of 4 per cent novocaine solution.
  1 tube sterile distilled water for hypodermics.
  1 tube of codeine hypodermic tablets, or capsules of sodium amytal if this drug is used
  1 tube tincture of green soap
  2 large cotton-wound applicators for applying iodine
  1 hand brush boiled and wrapped in sterile towel.
  Adhesive bandage scissors.
  Medicated alcohol (no corrosives).
  Medicine glass, with cotton for holding tubes.
2. Sterile gown with sterile towel for scrubbed hands.
3. Two pairs dry sterile rubber gloves with powder sponges.
4. Sterile packs containing as used: (a) Towel for protection of bed; (b) large table cover; (c) spinal puncture sheet (8-inch hole) sufficiently large to cover back and side of patient (d) four large gauze dressings ( ) six small gauze sponges

Fig. 137

CONTRAINDICATIONS TO THE SPINAL TEST

1 Old age, especially when accompanied by marked arteriosclerosis. The need for spinal tests in patients over sixty should be carefully weighed.
2. Presence of systemic conditions likely to produce marked lowering of general resistance, as, for example, carcinomatous and other cachexias, threatened or actual uremia, severe diabetes, advanced cardiac decompensation.
3. Any vascular or blood condition likely to result in persistent hemorrhage, such as hemophilia, increased coagulation time from other causes (jaundice, etc.) severe purpura, etc.
4. Intercurrent acute infections, especially of the respiratory tract, ear nose, and throat, and systemic disease in which bacteremia is known to exist, as in pneumonia, typhoid fever early meningococcic septicemia, streptococcal septicemia, etc. There is danger of transfer of the infection through the choroid plexus to the meninges and fluid.
5 Florid untreated generalized syphilis in the spirochetemic stage. Such patients should receive preliminary arsphenamin sterilization (1 or 2 injections)
6. Intracranial pressure, especially when associated with cerebellar symptoms or signs of brain tumor An examination of the fundus of the eye is essential (choked disk)
7 Rare cases of rapidly progressive mental or lower cord tabes.
8. Areas of infection of tissues in the needle path, as, for example, lumbar Pott disease with abscess formation of unknown extent, et
9. Obvious deformity of the lumbar spine which would make entry impossible.
10. Pregnancy

5 White enamel-covered tray containing (a) Two spinal needles with stylets removed and kept with their respective needles by wrapping points in cotton; (b) two 2-cc. all-glass syringes with three 20-gauge hypodermic needles ( ) hemostat for handling needles and so forth.
The contents of this tray should be laid between gauze, the hemostat on top of gauze and boiled in distilled water for ten minutes. The cover of the tray should not be removed, either during boiling or when draining.
6. Mercury manometer if operator uses one
7 Thermometer

Contraindications to Spinal Puncture.—These are summarized in Fig 137 since their preliminary consideration is an essential part of the technic.

Asepsis.—We regard spinal puncture as an invasion of the meninges in which a blunder in asepsis or technic may have the most disastrous consequences because of the inaccessibility of the parts and the low resistance of the tissues affected. We shall describe and illustrate therefore essentially a surgical technic of approach

Fig 138.

IMPORTANT POINTS IN SPINAL PUNCTURE TECHNIC

1. Know of contraindications before, not after. Take temperature.
2. Lumbar puncture presented here as the preferred method. Patient lying on side preferred.
3. With proper selection of needle, use of local anesthesia, and intelligent handling of patient, lumbar puncture is practically and often absolutely painless.
4. Preparation
   - ( ) Mild saline night before. Light meal.
   - (b) Thirty grains bromide or 3 grains sodium amytal night before if nervous.
   - ( ) Codeine hypodermic 1 grain, one-half hour before or 2 t 3 grains sodium amytal.
5. Talk to the patient: tell him t expect (1) local pinprick anesthetic; (2) ten t twenty seconds' toothache-like sensation, often absent, (3) twinge or shocklike sensation in the leg (1 in 4 t 10 cases)
6. Tell him further: (1) to relax, not try t help (2) t let the nurse double him up until chin and knees almost touch (3) not t straighten if hurt or spoken to.
7. For the operator
   - ( ) Skin sterilization with iodine removed by alcohol afterward.
   - (b) Use the fourth or fifth lumbar interspace (crest of ilium landmark), entering at the junction of the middle and caudal thirds.
   - ( ) Use 4 per cent novocaine if no idiosyncrasy
   - (d) Infiltrate skin and dorsal ligament.
   - ( ) Insist on perfect vertical plane for pelvis and shoulders coincidently W tch upper shoulder especially (Figs. 139 140)
   - (f) Handle only the hub of the sterile needle and stylet.
   - (g) Be sure the needle is entered horizontally stylet held in.
   - (h) Guard it with the left hand (Fig. 142)
   - ( ) Make no stabs or uncontrolled movements.
   - (j) Don't attempt t push past or around bone
   - (k) "Drill" if tissue (not bone) is tough. Don't force the needle
   - (l) Take new direction, but not a new puncture of the skin, by partial withdrawal (through the ligament) if necessary
   - (m) If marked pain occurs or blood appears, begin over. After blood use fresh needle
   - ( ) Don't overpass the canal. Learn t know the "feel" of entering. There is risk of hemorrhage in overpassing.
   - (o) Don't ream the puncture. If fluid is slow slight rotation of needle and having patient count may help.
   - (p) Never aspirate
   - (q) Not pressure.
8. The specimen
   - (a) Collect fluid not faster than drop second. Slower preferred. Control by stylet in needle hub
   - (b) Let 20 drops escape before collecting.
   - ( ) Three tubes, numbered seriatim.
   - (d) Total 8 t 10 cc
   - ( ) Cell count from Tube 3.
   - (f) Blood cells repeatedly present (microscopical) mark the amateur
   - (g) Not physical properties.
9. After-care
   - ( ) Warn of needle withdrawal.
   - (b) Have patient roll onto face
   - (c) One hour rest if ambulatory. Four t six hours if in bed
   - (d) If blood appeared, keep in bed t enty-four hours.
   - ( ) If possible routinely twenty-four t forty-eight hours rest in bed, little movement and conversation as possible
   - (f) Warn t report leg or bladder symptoms.
   - (g) Warn of headache treatment.
   - (h) Warn against rough travel for forty-eight hours.
   - ( ) See before final discharge
   - (j) Scott (thesis) and Ills (1941) have reported sedative unnecessary nd active movement or even light ork desirable immediately after puncture

THE ILL-PERFORMED SPINAL PUNCTURE PLAYS INTO THE HANDS OF NEUROSYPHILIS

Technical Considerations.—In Fig. 138 there is presented a summary of the technical considerations involved in spinal puncture illustrated by Figs. 139–142 inclusive. In reminiscences covering now some thousands of lumbar punctures, we would wish to impress, first, the importance of rapport between patient and operator We do not believe that with any except the best trained patient the physician should attempt spinal puncture unassisted. There is great danger in attempting any form of spinal manipulation on uncooperative patients without proper assistance and it is safety first to have someone hold every patient's neck and knees during the puncture.

After seating himself the operator should address the patient before making a move. Most patients have a justifiable anxiety about the test. This is greatly reduced by sodium amytal. The spinal column seems a peculiarly

Fig 139.—Patient lying on the right side, incorrect posture. Note that the upper shoulder has dropped forward and the plane of the shoulders and pelvis is no longer vertical. The twist of the spinal column in this position may make entry difficult or impossible.

vital structure to the average man or woman. The unfortunate term "puncture" reminding one of a collapsed tire, creates a disconcerting impression and should not be used toward patients, "test" being used instead The operator explains that a local anesthetic will be used, that the discomfort, which is slight, will consist, first, of the pinprick of the hypo needle a slight burning sensation, sometimes a feeling described as resembling a toothache for ten seconds, and perhaps, in occasional cases, a jar or slight electric shock in the leg, if the needle touches a "cord" (filament of the cauda) A skillful operator anesthetizing the ligament as well as the skin, can perform puncture after puncture without the patients even being aware that anything has been done The preparation of the patient by warning him exactly as to what is coming, and cautioning him to hold still is of the greatest possible value, not only in preventing accidents but in getting the patient into an attitude of confidence

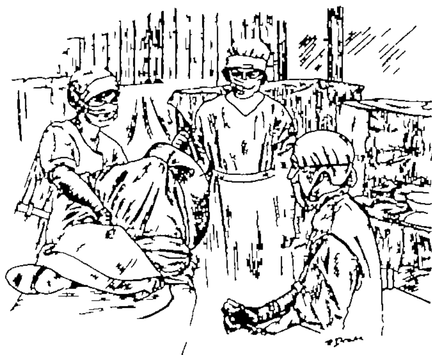

Fig 140.—Correct posture, shoulders and pelvis in the same vertical plane. Note that an assistant holds the neck and knees t prevent unexpected straightening of the back after the needle is introduced.

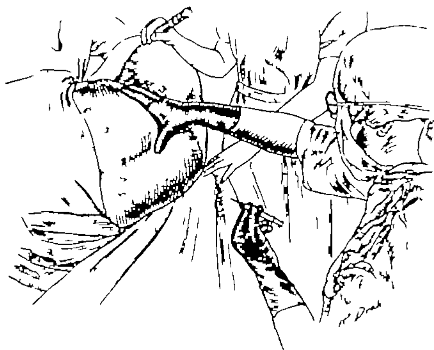

Fig 141.—Establishing the position of the fourth interspace using the iliac crest as guide The back has been painted with iodine. A sterile sheet ith small opening may be used

in the operator indifference to the test and willingness to submit to it again, whenever necessary in the future. The impression made by the first test, if poorly done may absolutely preclude a second.

Entry of the Canal.—This should in general be made between the third and fourth or the fourth and fifth lumbar vertebrae In some cases it may be made between the fifth lumbar and first sacral, or between the second and third lumbar but never above the second lumbar vertebra. The line joining the crest of the ilia passes across the spinous process of the fourth lumbar vertebra. Careful palpation is an invaluable preliminary With the Greene type of point, the skin and ligament may be "drilled" by rotating the spinal needle. The puncture of the dura is marked by a sudden loss of the sense of resistance which can only be learned by experience With the blunter types of

Fig. 144.—Introducing the needle bet een the t fingers of the left hand, with the right hand resting upon the left wrist as guide and guard against sudden movements or excessive pressure which may break the needle

needles this is less marked than with the sharper When this "dropping-off place" is reached the operator should go no farther but rem ve the stylet and if the needle point i in the canal fluid will appear almost at once

Management of Immediate Complications of Lumbar Puncture.—Those complications which must be met by the operator on the spot include

1 **Inability to Enter the Canal.**—Consider the possibility of bony deformity hypertrophic spondylitis, trauma, sacralization of the fifth lumbar vertebra, tc. Note whether the bowing of the back is sufficient, and have the attendant increase it *after withdrawing the needle point to the skin level.* Be sure sacrum and shoulders are in a vertical plane. Aim lower or move the needle to another part of the interspace and change direction keeping needle in the same puncture wound and moving the skin about. As a last resort, enter another interspace after reanesthetizing Keep cool and silent.

2 **Inability to Obtain Fluid After the Canal Seems to Have Been Entered.**—True "dry taps" must be excessively rare in fact, though common in amateur experience Most dry taps are technical failures. If you believe yourself in the canal withdraw the stylet. If there is no result when you believe yourself in the canal withdraw the needle slowly taking out the stylet from time to time, or even leaving it out for a short distance You may have over passed If there is no result, re-estimate your distance, replace the stylet, and go a little farther in. Never advance a needle with the stylet out. If this fails, take it for granted you are not in the canal and proceed as with (1)

Slow Drip, Clear Fluid.—If a slight push or pull on the needle will not increase the flow be patient and wait. The slower the flow the better for the patient. It is inadvisable to rotate the needle under such circumstances, unless absolutely unavoidable since it may inflict additional trauma on the dura. Having the patient count, or engaging him in conversation (caution) or having him take deep breaths hastens the flow Pressure made by the thumbs over the jugular veins will also do so.

Fig. 143.

CROSS-ROADS CLINIC LUMBAR PUNCTURE

1 Careful exclusion of ineligibles (age arteriosclerosis, et).
2. Privacy—room cleared.
3. Work concentrated t single session.
4 Experienced operator or visiting team.
5. Stool or chair technic patient sitting.
6. One assistant to hold patient, handle tubes.
7 N prel minary sedative no warnings or instructions.
8. Local nesthesia not necessary but preferred.
9 Asepsis, scrubbed hands, no gloves or gown.
10. Care bout
 ( ) Discarding first 20 drops.
 (b) Labeling tubes on spot, no mix-ups.
 ( ) Prompt transfer t laboratory and adequat handling and examination.
11. After test, patient stands up, dresses, walks out, told may do light work, report and lie dow if headache or leg pain.

Gush of Fluid.—The normal flow of fluid from a successful puncture varies with the needle and the position in the canal, but seldom exceeds 70 drops per minute If the fluid shoots out in a stream or gushes in a rill, immediately *reinsert the stylet or cover the opening with the finger since sudden release* of pressure may be serious. Control by keeping the tip of the stylet in the opening and draw *very slowly* and not in excess of 3 to 5 cc

Blood-tinged Fluid.—A fluid which is visibly tinged with blood is unsuited for a cell count. The sources of blood are (1) ill fitting stylet (2) removing stylet too often to see if canal has been entered (3) moving needle back and forth with stylet out (4) needle point in a vein (5) trauma to the venous plexuses of the dura which permits blood to enter the canal (6) blood from hemorrhage into the canal at a d tance, a from cerebral injuries, trauma, apoplexy etc

Traces of blood when the fluid first begins to flow are evidence of technical error Gross blood contamination necessitates a repetition of the puncture at a higher level and at once *Use a fresh needle* A steady flow of bloody fluid means injury to a vein or venous sinu and further attempt to get a clear

fluid are for the time being useless Blood even microscopical, is usually one of the earmarks of the inexpert operator Overpassing entering the plexus against the vertebral body and removing the stylet too soon or too often are the commonest sources of this difficulty

When a fluid has shown definite evidence of blood contamination it is especially important that the patient be kept absolutely quiet in bed under observation with an ice-cap to the spine for at least forty-eight hours

Collection of the Specimen.—*Allow the first 30 drops of a clear fluid to escape in order to remove the last traces of slight but inevitable blood contamination from the needle* The specimen is then collected in three 5-cc. tubes which, if not immediately removed to the laboratory must be corked with sterile corks (not gauze or cotton) In all other particulars the specimen must be handled exactly as a specimen of blood for serological test. The three tubes are numbered serially and the third is used for the cell count. The total amount of fluid removed should range from 8 to 10 cc., if all tests are to be done. Some observers feel that if the manometer pressure of the fluid exceeds 20 mm. of mercury there is risk of medullary block if spinal fluid is removed for diagnosis. Normal manometer readings range from 6 to 20 mm. Hg or 40 to 200 mm. water A sudden spurt of fluid is certainly a warning, but pressure estimates from needle flow are untrustworthy for the slighter variations are influenced by bore and position of the needle and placement in the cavity or concealed obstruction. Careful note should be made of physical properties, color turbidity and coagulation of the fluid, if it occurs. Fluid flow can be absolutely controlled by the tip of the stylet in the opening of the needle.

The nonoperative complications of spinal puncture are considered in the next chapter

TECHNIC OF CISTERN PUNCTURE

Cistern puncture performed by Obregia in 1908 but standardized and developed by Dixon, Weed, Ayer and others, and performed in this country by Ayer and his associates in 1919 is at the present time the subject of enthusiastic advocacy by Spiegel, Mennenheimer and Jacobi. Spiegel and Jacobi speak of the "fear complex" which still justifiably interferes with the wholesale popularization of the procedure In spite of repeated and enthusiastic endorsement of cisternal puncture by competent men (Kulchar (1940) Franks (1940), Alexander Fox and Schoch (1943)) it is not t be commended t practitioners and is limited at this time to its applicability to those who can take training for it on the cadaver and use it under controllable conditions. Cistern puncture is claimed to have many advantages, including relative painlessness, freedom from postpuncture reactions, including headache, and relative indifference of the patient to the procedure, which permits its indefinite repetition (Mennenheimer) Spiegel claims that with perfected technic bloody fluids are rarely met with and relatively large amounts of fluid may be withdrawn with no after-effects.

The dangers of cistern puncture, particularly by the direct, or original Ayer technic, consist, of course, in overpassing with injury to the medullary structure and hemorrhage from the dural plexus. The depth of the cistern at the point of puncture is pproximately 1 t 1½ cm., which allows somewhat greater margin than in the lumbar region; modified however by the presence of the medulla itself rather than the relatively much less easily injured cauda equina.

Two technics of cistern puncture exist, the direct technic of Ayer[*] using as the line of entry along which the needle is directed, an imaginary line joining the glabella and the midpoint of the external auditory meatus. American advocates of cistern puncture now commend, however the indirect technic of Eskuchen, performed with needle carrying stop, as devised by Spiegel Spiegel has adopted over period of years combination of the direct and indirect methods because it is impossible to fortell before puncturing the dura whether one will be able t touch the posterior edge of the foramen magnum of the occipital bone.

In the performance of the Eskuchen puncture, the patient may sit, or lie on one side, the

* This is the technic as described by Jacob.

landmarks being clearer in the sitting position and flow of fluid only being obtained in the lying position which may be carried through without assistance (Spiegel, personal communication, 1943, prefers to have the patient in the lying position. In the sitting position one does not always know when the dura has been punctured, as no fluid will flow on puncture. This necessitates the use of a syringe thus adding another hazard since the needle may be moved in attaching the syringe). The head is moderately flexed on a small, hard pillow which must be high enough to impart to the cervical spine a perfectly horizontal position. The head must be, moreover in a perfect front-to-back plane and not turned to one side or the other The important external landmarks are the occipital protuberance, the spinous process of the axis or second vertebra, and the deepest depression at the back of the neck. Placing the left index finger on the external occipital protuberance, the operator palpates downward in the middle line closely hugging the occiput, until the fingertip reaches the deepest depression. Immediately behind this spot will usually be found the spine of the axis, which is the first essential bony landmark. About ½ cm. above it the needle is inserted, pointing in the approximate direction of the outer end of the eyebrow

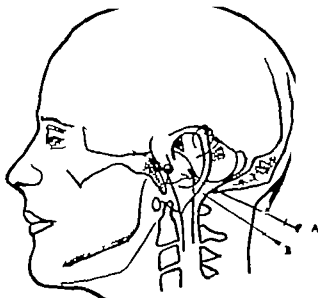

Fig. 144.—Sagittal section of head showing anatomical relations involved in cisterna puncture. (Courtesy of Dr Leo Spiegel.)

From this point on, no definite landmarks are given by Eskuchen. Advancing the needle along the line thus indicated (toward the eyebrow) the point first encounters a bony obstacle *which is the squamous portion of the occiput. The needle handle is then lifted repeatedly and* slightly the point being advanced by successive movements along the edge of the bone to the exact spot at which the point slips off the bone and meets the elastic resistance of the ligament covering the atlanto-occipital membrane. *If the needle point at first introduction falls below the* occiput, it may by depressing the handle, be directed upward until the bony landmark *is found.*

When the needle point slips off the occipital bone the operator removes the stylet and again advances very slowly and cautiously for a distance varying from ½ to 1½ cm., the latter marking the outer limit of safety A few millimeters is usually enough. A feeling of a dropping-off place may be absent, which makes the removal of the stylet the more important. The amount of fluid removed and so forth are identical with those in lumbar puncture.

Mennsenheimer in an examination of 10,000 punctures, found reports of 7 fatalities, most of them in the early history of the procedure. The list of minor mishaps given by Jacobi is important enough to deserve separate study and his article together with the writings of Spiegel, is commended to those who desire to study the technic on the cadaver in preparation for its use on patients.

TECHNIC OF INTRASPINAL MEDICATION

The details of intraspinal therapy are fully discussed in the first edition of this work, pp. 209–214 and 260–273. The reduction of this procedure to relatively minor importance with the advent of tryparsamide and malarial therapy justifies only condensed description of the Swift Ellis procedure at this point.

The Preliminary Intravenous Injection.—The patient is given intravenously an injection of the arsphenamine which has been adopted for his treatment, the dose ranging from one-half to two-thirds the adult weight maximum. At an interval ranging from ten to sixty minutes, and usually forty minutes after this injection, 30 cc. of blood is drawn from the cubital vein through large needle into each of two large sterile centrifuge tubes. This blood is allowed to stand for one hour at room temperature and the clot is then separated under aseptic precautions from the sides of the tube with sterile knitting needle. It is then placed in the ice-box and allowed to cool and shrink, which affords larger yield of clear serum. Both serum and clot are then centrifuged

Fig. 145.—"Second pipetting" in the Swift Ellis intraspinal technic. After the serum has been separated from the clot by the first centrifuging, it is pipetted off ("first pipetting") and recentrifuged at high speed to throw down the last traces of red blood cells. Special care must be taken to avoid aspirating blood cells into the second pipetting, so that an excess of serum above the amount required for treatment is essential.

in high-speed centrifuge at 2000 revolutions, for ten minutes. It is extremely important that each tube be properly balanced by weight against similar tube containing water since at the speed the centrifuge is run, serious damage to the bearings and possible wrecking of an improperly balanced tube follows neglect of this precaution. The strictest asepsis must be maintained throughout this and subsequent manipulations.

After the first centrifuging, the supernatant serum is pipetted off with 25 cc. pipet (Fig. 145) into similar centrifuge tube and centrifuged again at the same speed for fifteen minutes to throw down the last of the red blood cells, which are responsible for marked irritative symptoms in the spinal canal. A second pipetting off of 25 cc. of the serum is then done, care being taken not to draw off the serum within ½ inch of the bottom of the tube from the second centrifuging. This tube of double centrifuged serum is then placed in the ice-box over night. At this point the Ogilvie arsphenamine reinforcement may be practiced, if desired. If the Swift-Ellis technic is followed, the serum (45 cc.) is placed in the warming oven at 56 C. for seventy minutes. The

entire procedure, including the introduction of the serum into the spinal canal, may be completed in one day after the technic proposed by Kolmer the intravenous injection being given in the morning and the intraspinal treatment in the afternoon.

The technic of introduction of fluid into the canal calls for the equipment shown in Fig. 146, the needle being introduced as in lumbar puncture. The buret with tubing and adapter is attached to the needle after free flow of fluid is obtained, and 30 cc. allowed t collect in the buret. The tube is pinched repeatedly during this process to allow contained air t escape into the container The specimen for spinal fluid examination is obtained from this fluid and the remainder discarded The emptied buret is then allowed t fill once more with from 20 to 40 cc. of fluid, depending on the patient, and t this fluid the 25 cc. of auto-arsphenaminized patient serum is carefully added, good mixture being secured. By raising the buret container above the level of the needle, the mixture slowly flows back into the canal. The container is then disconnected and the needle withdrawn, as in spinal puncture.

As soon as the treatment is completed, the patient is rolled over on his face and the after care is that of spinal puncture (see p. 320) except for the closer watch kept for complications and the palliative relief of leg pains, if they occur

In the effort to treat the base of the brain and the pathologic condition of primary optic atrophy it is essential to carry the fluid introduced in the lumbar region, higher up the canal This may be done by the Gennerich double puncture technic, in which two punctures are made,

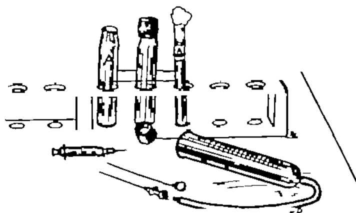

Fig 146—Equipment for administration of intraspinal arsphenaminized serum. The graduated buret has capacity of 40 t 75 cc A specimen of spinal fluid is collected before introducing the serum.

one between the second and third and the second between the fourth and fifth lumbar vertebrae, following the usual technic T enty-five cc. of fluid is allowed t flow int the upper buret and as much additional into the lower can be collected. During this process the head should be high and the pelvis low As much fluid as possible should be drawn into the lower container Most of the fluid in the upper container is discarded, the Swift Ellis serum is added, the fluid is allowed to flow in, while the lower container is held in reserve. The head of the patient is then lowered and the buttocks elev ted and the contents of the lower container (caudal) is allowed to flow in, carrying the previously introduced arsphenaminized serum up the canal toward the base of the brain. That the purpose is accomplished is attested by the fact that there are no lower-cord symptoms following the treatment but that posttreatment pains may appear in the arm and about the waist together with dull headache.

Intracisternal treatment may be given by the Swift Ellis technic in preference t the Gennerich procedure and the patient may also simply be more or less stood on his head after the ordinary lumbar Swift Ellis treatment in the effort to secure upper-cord and basilar effect.

The complications of intraspinal medication include pains in the legs, sharp and knifelike suggesting those of tabes dorsalis; and evidence of irritation of the sexual and bladder centers of the cord. Aspirin and codeine may be used for relief Fever is an unusual occurrence, headache is much less common than after spinal test alone. Significant cord irritation includes the development of saddle anesthesia, which may be transient or permanent, and retention of urine sometimes not complained of by the patient for number of hours or longer The previously existing

Fig. 147

COLLECTING AND HANDLING THE BLOOD SPECIMEN FOR THE WASSERMANN TEST

1. Blood is usually drawn from the cubital vein in the bend of the elbow. In order to distend the vein with blood, tourniquet must be pplied to the arm to stop the venous return.
2. Procedure should be aseptic throughout. Specially prepared tubes are used, supplied by the laboratory and usually sterilized.
3. Syringes and needles used in drawing the blood must be boiled for five minutes in clean water. Chemical disinfectants or alcohol must never be used.
4. The skin is disinfected with alcohol or iodine. Do not use agents which leave prolonged stain.
5. Timid patients or those who may faint should lie down before the test. This is the better practice in all cases.
6. Not less than 5, and better 8 or 10 cc. of blood are necessary for the examination. Some Wassermann tests can, however be performed on as little as 1 cc.
7. In drawing blood with the syringe remember to work quickly for it will coagulate and ruin the syringe. Expel it at once into the tube provided by the laboratory and pull the plunger from the syringe barrel.
8. Keep the tube cont ining the blood right side up: cork it at once and label it. There is no worse crime in nursing than t mislabel or mix up bloods for Wassermann tests. You may pin a diagnosis of syphilis on to the wrong person. Observe the following precautions:
   (a) Paste one of two perforated gummed labels attached to each other to the laboratory sheet.
   (b) Fill them out in duplicate in ink or indelible pencil ith name of patient, date and physician to whom report is to be made.
   (c) Draw the patient blood and expel into the tube, and *then and there*, before separating patient and blood, cork the tube, separate the duplicat perforated label, above mentioned, from its fellow glued t the report slip, and past the duplicat on the tube of blood, fastening it still more securely by rubber band.
   (d) Then, and only then, may blood specimen and patient be separated.
   ( ) Never draw another specimen until the first is completely disposed of.
   (f) Mistakes begin when patient and blood are separated before labeling, and label and report slip are not automatically duplicated.
9. Allow the tube t stand t room temperature for fifteen or twenty minutes. This will give time for clotting. Do not tip the specimen around in the tube.
10. Bloods hich are not delivered to the laboratory t once must be kept in the ice-box from the time clotting occurs.
11. Bloods should be delivered to the laboratory t the earliest possible moment so that they may be centrifuged and inactivated.
12. Handle tubes with the greatest care. They have trick of slipping through the fingers and striking hard objects, and a blood specimen once lost may never be replaceable.
13. Report any breakage at once. Never set tubes dow in glass tumblers or other containers without having something soft like cotton on the bottom.
14. Do not try to carry a number of tubes simply by putting a rubber band around them. Always hold one hand under them.
15. Never deposit blood specimens t random anywhere including the laboratory. Have definite place for them, preferably in the ice-box. Never lay them down on a table at room temperature or give them t some by-stander unless specifically instructed.
16. Blood may in early cases be infectious. Wash it t once from your hands. Do not spill it around, and if you splinter test tube, report yourself t once t physician t be sure that you have not been infected by cuts or minute particles driven into the skin. Pricks from needles used in drawing blood are even more serious. Report them t once.
17. Blood which spurts into the mouth or strikes the face or eyes is serious and you should report yourself at once.
18. Blood specimens from infants may be obtained from the infant or maternal end of the umbilical cord at birth. I older babies stab in the heel ith small trocar will, with some effort, yield enough blood for single stage test. The jugular vein can be entered ith small needle and syringe ith proper assistance t hold the head. Entering the superior longitudinal sinus is done but not recommended. Most children have elbow veins accessible to competent operators.

lower-cord symptoms are sometimes accentuated and myelitic symptoms appear in rare cases. Intercurrent infections may complicate the picture and patients should be warned of exposure after intraspinal treatment. Meningeal infection occurred once in our experience in 8000 injections. The mortality in our experience was two in 8000 treatments.

COLLECTING AND HANDLING THE SPECIMEN FOR BLOOD SEROLOGICAL TEST

The instructions summarized in Fig 147 were developed for nurses but they have proved useful enough in instructing medical students to justify their introduction here. The one-man technic illustrated in Figs. 148–151 inclusive can be used in dispensaries and crowded services. The needle used is the 16-gauge or a 20-gauge large antitoxin needle to which a 4-inch piece of

Fig 148.—Applying the tourniquet (rubber bandage) in one-man Wassermann technic, sitting. The ends of the bandage are crossed on the front of the arm under tension, twisted upon each other and the patient seizes the twist between thumb and index-finger of the right hand The fist of the left hand is firmly pressed against the operator's knee. At the conclusion of the blood drawing the patient simply releases the "twist" and, as the tourniquet drops off, presses his thumb upon the cotton pledget covering the puncture (Fig 150)

rubber catheter has been attached The Kolmer modification of the Keidel tube (Fig. 168) is supplied by most private laboratories with proper mailing containers. The tourniquet is applied as in Figs. 150 151 The arm must be fully extended and the closed fist tightly pressed against the operator's knee or hip if standing The patient releases his own tourniquet when the specimen is obtained and presses the thumb of his free hand on the pledget as it is placed over the needle.

Collection of Blood Specimen from Infants.—A fair yield of blood which should not be less than 1 and preferably 2 or 3 cc may be obtained from infants or persons with difficult veins by constricting a finger or the great toe and making a deep puncture with a bloodletting stylet or an acne lance The blood can be collected with an eye-dropper (previously sterilized) and dis-

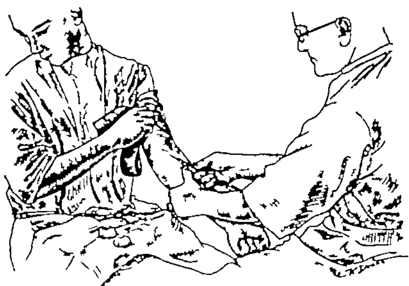

Fig. 149.—One-man Wassermann blood-drawing technic. Traction with the left thumb fixes the vein, and syringe or tube is held in the right hand as in the syringe technic of injection. The patient presses his fist against the operator knee and releases his own tourniquet. A similar technic may be used with the patient lying down

charged quickly into a small test tube standing in a tumbler A Wright capsule which consists of a bulb drawn into a capillary tube at both ends, one end being curled up and both ends being sealed in the flame when the specimen

Fig. 161.—Raising the arm overhead, by emptying the vein, decreases the tendency to bleeding and suggillation.

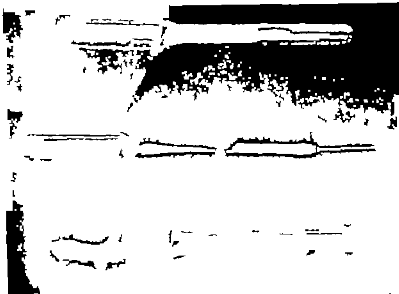

Fig. 162.—The Keidel vacuum tube for collecting blood specimens. The needle is enclosed within the sterile glass cap. The capillary neck of the glass tube, within the rubber tube, is broken or crushed *after* the tube is pinched or closed, or after the needle is introduced into the vein. The blood flows in to fill the vacuum. Clotting seals the needle and the glass cap is put on. The Corner modification inserts a glass window behind the needle to demonstrate the presence of blood (needle in the vein) before breaking the capillary tube.

is collected may be employed In newborn babies the blood may be obtained from the umbilical cord, but some investigators distrust the ordinary serological technics as applied to this blood and it is preferable to get blood later from the infant, for reasons discussed in Chapter XXI The jugular vein may be employed, and likewise the superior longitudinal sinus but these procedures are not recommended for general use

TECHNICAL ASPECTS OF FEVER THERAPY

Because of the growing field of usefulness for fever therapy in the various phases of syphilis, it is appropriate to discuss the technical aspects of this form of treatment in this chapter

The Malarial Therapy of Neurosyphilis

The status of malarial therapy from the nonspecific standpoint has been discussed in Chapter V There can be no question of the distinguished character of this contribution to the modern treatment of one of the most terrifying and hopeless phases of syphilis. It takes rank today as probably though by a somewhat narrower margin than enthusiasts admit, the most effective single method of dealing with late resistant neurosyphilis and particularly with paresis. There is, however good ground for the feeling voiced by conservative observers including Steiner in the massive Handbuch summary that a procedure such as malarial therapy which involves the inoculation of a patient with one disease to cure him of another has an intrinsically repugnant quality which, despite its effectiveness, still gives it the flavor of a makeshift. This, plus greater controllability and wider adaptability accounts for the intense interest in other forms of induced fever therapy

Historical Considerations and Earlier Literature.—The originator of malarial therapy Wagner-Jauregg of Vienna, in 1887 discussed the influence of intercurrent febrile disease upon the course of psychoses and began his experimental study by the use of Koch Old Tuberculin in the treatment of general paresis, reporting favorably on the method in 1909 Pilcz confirmed the observations of Wagner-Jauregg. Wagner-Jauregg later employed antityphoid vaccine for nonspecific effect, and finally came to the conclusion that the actual presence of an infectious disease was required for the best therapeutic results and, accordingly in 1917 took up systematically the inoculation of paretics with tertian malaria. The results in 9 instances were very favorable and continued experience of the method led him in 1921 to report on 200 cases of general paralysis, 50 per cent of which had gone into such complete remission as to be able to resume their former occupation. For his achievement Wagner-Jauregg received the Nobel prize in medicine.

The literature even up t 1936 includes almost innumerable reports of smaller groups of cases. There is definit tendency to follow the current of enthusiasm and to discuss success rather than failure, achievement rather than technic. The American experience (Cooperative Clinical Group Subcommittee on Fever Therapy 1940), comprising 1100 patients treated with malaria and 880 patients treated with artificial fever lends definite support to Simpson (1940) view that while considerable controversy has arisen regarding the relative merits of the various methods of producing artificial fever by physical means, the fact remains that the type of apparatus chosen for this work is distinctly secondary consideration. Much more important is the adequate preliminary training of the physicians and nurses ho are selected to engage in this work. In the hands of skilled orkers, employing satisfactory apparatus, few difficulties will be encountered. If however the ork is undertaken by untrained persons it is fra ght with danger

The insistent dinning of the mortality argument against malaria into the ears of its proponents is slowly leading t better evaluation of the question and clearer delineation of indications and contraindications. The argument at first advanced that the mortality of paresis itself was so high that mortality incurred in its treatment as *ipso facto* of small significance has given place to more studied consideration particularly because of the advocated extension of this well as other forms of fever therapy to the treatment of all types of syphilis. Tryparsamide ha

served as valuable foil in bringing out both the merits and the deficiencies of malarial therapy in American practice.

The Practical Equipment for Malarial Therapy.—Treatment by inoculation malaria is a specialist's method appropriate to centers and dangerous when undertaken by the inexperienced or without adequate organization and facilities. It is at its best when a group of well-organized hospitals such as some of the state groups of hospitals for the insane in this country combine on the development of a technic, draw their strain of inoculating plasmodium from a central laboratory-controlled source and the chiefs in direct contact with patients are able to give the necessary time and thought and have developed the necessary experience to meet the rather formidable array of complications which this form of treatment, especially when applied to a difficult or damaged material, will inevitably produce. While the isolated physician and the small country hospital may succeed in dealing with the earliest cases in the most robust individuals, they will inevitably be brought to book by a fatality if their success with a favorable material leads them to extend their activities into the field of the unfavorable. As many observers have emphasized and as those, such as Osborne, Cole, O'Leary, Mayne and Young and Moore in this country have clearly shown, the low mortalities of 0.5 to 1 or 2 per cent are the products of stringent selection of an appropriate material as well as experience in dealing with it.

The minimum requirements for the proper use of malarial therapy are an organized hospital service in which the chief makes daily rounds and personally sees the patients under treatment. Osborne has well emphasized this point, which Kemp and Stokes found applicable even to the relatively milder procedures of fever therapy. A successful malarial service cannot be conducted under the supervision of interns. A thoroughly trained, responsible, and autonomous nursing head is a second essential. "Breaking in" pupil nurses on sick, uncomfortable and often critically ill patients except under the most constant and expert nursing supervision, is an injustice to the method as well as the patient. A large amount of laboratory work, as will presently be seen, and the closest and most economical relationship between ward, private room, and laboratory is essential. A scale of maximum or even average charges for the repeated tests essential in the proper control of a malarial case swamps the majority of patients by its unbearable expense. Successful malarial therapy therefore has its business side, more critical sometimes even than its medical phase, and this fact alone is likely to lead to its increasing concentration in the hands of organizations and of the state. It is notable that even in a country still the center of the most individualistic type of medical practice, namely, France, steps were being taken to organize a system of centers for malarial therapy which should do away with its hedgerow exploitation by each and every individual or small group that can beg or borrow 5 cc. of malarial blood. Points at which time may be saved to the patient and, incidentally, expense, include admission to the hospital with the first chill instead of on inoculation, and the induction of febrile reaction with shortening of the incubation by the use of typhoid-paratyphoid vaccine in the malarial incubation period. Entire lack of medical supervision during the inoculation period may, however, be very serious, for apparently malarial deaths have been known to occur before the actual onset of the febrile siege.

The Field of Malarial Therapy.—General paralysis, early and late, including the field of *paresis sine paresi*, is the ideal and the chief field for malarial inoculation therapy. Subordinate to it is the group of resistant neurosyphilitic manifestations which include such conditions as primary optic atrophy and the gastric crises of tabes dorsalis. Few observers have been able to report satisfaction with their application of malaria to the treatment of tabes. Among them are Wile and Hopkins. Nonne rates malarial therapy in tabes as by no means the first choice. Bering and Dreyfus have emphasized the value of the dampened or abortive malarial course in preference to the usual siege

in patients with tabes. Not only then, is paresis the major field for malarial therapy but earlier and earlier paresis. The striking differences in mortality and therapeutic results are apparent in the tables

Malaria in Early Syphilis.—The question inevitably arises whether the use of malaria cannot be extended forward into the life history of the infection to the primary and secondary stages, both for its possible preventive value and for its aid in reversing resistant serological tests and diminishing the general severity of the disease.

This hope was extensively and enthusiastically studied by Kyrle and by Kerl. From their large experience Kerl insists that it is premature to advocate malarial therapy as protection against neurosyphilis, although its use from the second t the sixth year of the infection is rationally justifiable Several other observers have agreed that there can be no possible reason for using malarial therapy before the second year of an ordinarily progressing syphilitic infection. Von Barde found that the adenitis and eruption of secondary syphilitic infection continued to develop even when malarial therapy was used in the seronegative primary stage and instances have been observed in which malaria has induced malignant precocious tertiarism. The question as to whether previous malaria actually protects against the development of neurosyphilis must, then, be tentatively answered in the negative in spite of the often quoted statistics of Mattauschek and Pilcz, of 105 paretic army officers, not one of whom gave history of an acute febrile infection during the first few years after acquiring syphilis, while of 241 syphilitic patients ho had cute infectious diseases during that period, not one developed general paresis. Kirschbaum, in contravention of this conception, reports 10 patients with general paresis who had had malaria during the secondary stage of their syphilis W have moreover seen confirmation of the belief that patients who have had malaria in early lif derive little benefit from it and i some cases are markedly resistant even to infection with it (Greek patients particularly among whom malaria was prevalent) when they later develop paretic neurosyphilis.

It is then, we think, safe to say in accordance with Zieler s summary of the literature that there is no justification for the routinization of malarial therapy no reason for its extension to the treatment of early syphilis especially as a substitute for thoroughgoing treatment with arsphenamine, bismuth and mercury and that its primary and established field of usefulness is paresis and preparesis, other aspects of established neurosyphilis in relation to its effectiveness being still under study and not fully evaluated. The combined treatment of early syphilis with other types of fever and chemotherapy may prove to be one of the most efficient modes of dealing with the disease as a whole.

Indications and Contraindications.—These we have attempted to summarize in Fig 153 certain points will bear special discussion The control of the strain of malarial organism will be presently mentioned, but it should be understood more generally that unless a reliable strain of fairly constant characteristics is being maintained or can be procured from a center dangerous and disconcerting results may ensue. Wagner-Jauregg especially emphasizes that no person who has ever been in or near the tropics should be allowed to serve as a donor no matter what his condition, and mosquito inoculation should be condemned on the score of the presence of sexual forms which conduces to relapse of the inoculated malaria after treatment with quinine. Wagner-Jauregg has also emphasized the importance of blood-grouping in advanced inoculation and the use of a donor of a different group from that of the patient in order to prevent the appearance of a quotidian type of fever with its exhausting daily attacks. Moore (text, 1941) on the other hand notes increased facility of inoculation and shortened incubation when the donor is of the same blood group using a large inoculum.

The question of an age limit for malarial therapy is a difficult one. The known extensive character of cardiovascular involvement, probably the gravest single contraindication to any form of fever therapy in patients with long standing syphilitic infections, and the very great difficulty of accurately evalu-

Fig. 185.

MALARIAL THERAPY

Indications	Contraindications
1. Early paresis and preparesis in young robust persons.	1. Decentralized inexpert control and inadequate facilities (not practitioner's method).
2. The same conditions in older patients without contraindications.	2. Unsatisfactory strain of malarial organism.
3. Presence of neurosyphilitic or other optic nerve disease contraindicating tryparsamide.	3. Donor of same blood group as patient (Wagner-Jauregg).
4. Resistant nonparetic asymptomatic neurosyphilis (in late latency, not early syphilis).	4. Old age. The age limit should be based on physical status rather than years.
5. Where a reasonable trial of tryparsamide has failed (one year) and no serious contraindications to malaria appear.	5. Definite cardiovascular disease, especially coronary and myocardial, and including arteriosclerosis.
6. Optic atrophy and gastric crises, persistent lightning pains when not otherwise contraindicated.	6. Pulmonary tuberculosis, latent or active.
	7. Chronic alcoholism.
	8. Marked diabetes (mild is not).
	9. Severe anemia.
	10. Obesity.
	11. Persistent thymus.
	12. "Galloping" paresis.
	13. Advanced tabes with severe ataxia, decubitus, pyelonephritis.
	14. Pregnancy.
	15. Kidney disease.
	16. Marked hepatic disease or insufficiency or splenic disease.
	17. Severe debility.
	18. Last stages.

Discussion

1. Advantages of malarial therapy. On the whole, probably the highest effectiveness, risks disregarded, of any single form of treatment for resistant neurosyphilis; accomplishes much in a short time; institutional features control therapeutic flare-up without family and social difficulties, places responsibility and control in hands of experts; the best single chance for result in difficulty controllable or uncooperative cases.
2. Disadvantages of malarial therapy. A center or institutional method, for the experienced only; not always available; mortality 0.5 to 10 plus per cent; temporary dislocation of occupation and economic status, some stigmatization; difficulty of maintaining safe strains of organism in small institutions; discomforts of stormy course; not adapted to the debilitated, badly complicated case.

ating such involvement has led us, from a limited number of personal observations, to set age forty-five as an approximate limit beyond which anything approaching the over-ready or routinized employment of malaria becomes particularly dangerous. None the less it is true that patients as old

as seventy years have undergone malarial therapy without ill effects but such occasional strokes of luck are by no means guides to an intelligent therapeutic procedure Perhaps it might fairly be said that the age limit should be based upon the physical characteristics of the patient rather than his years, for the obvious differences in the resistance and physical resources of two different types of the same age is too evident to need comment.

Cardiovascular disease, and particularly coronary and myocardial insufficiency is the greatest single outstanding contraindication to malarial therapy Generalized arteriosclerosis is perhaps of equal seriousness. The cardiovascular involvement need by no means necessarily be syphilitic—in fact we have seen that certain observers rate cardiovascular syphilis in conjunction with neurosyphilis as of a relatively less advanced and serious type Steiner however states that by far the largest proportion of the deaths in the literature have a cardiovascular slant, and emphasizes the difficulty of using any criteria dependent on sharp differentiation between uncomplicated aortitis and aortitis with coronary involvement and myocarditis Wagner-Jauregg, in his more recent statements believes that vascular syphilis in patients with paresis is often made worse rather than better by malaria. Moore s very instructive case (Moore Danglade, and Reisinger) in which a patient with grave cardiovascular syphilis was wheedled through two malarial sieges, is, however an excellent illustration of the possibilities under expert care, and with the use of quinine or bismuth to diminish the severity of the chills and control their frequency it may be possible to carry a patient through two short malarial sieges instead of one longer one. In fact, Wagner-Jauregg recommends this method for more general use in preference to the severe strain upon the patient s organization of a continuous session of 16 to 18 chills. Kihn believes that the really serious cardiovascular risks to the patient come at the close of the malarial siege as quinine is being used, and advocates initial small followed by later heavier doses as a method of "sliding the patient out" of his malaria.

Pulmonary complications rank high among the serious incidents of malarial therapy and even the milder forms of fever therapy have, in our experience, *shown a definite tendency to light up latent tuberculous foci at the apices* The presence of active tuberculosis is therefore generally accepted as a strong contraindication to malarial therapy and the more conservative general reviews include known latent tuberculosis also

There is a definite rise in blood sugar during fever therapy and mild diabetics can have this complication controlled by insulin. In the graver cases, with their presumed arteriosclerotic damage and susceptibility to intercurrent infections, malarial therapy is definitely contraindicated.

Moderate grades of anemia do not contraindicate malarial therapy provided an adequate microscopical control of the blood is exercised. Schilling observed the marked tendency toward regeneration in the anemias of induced malaria, so that the complication need rarely be serious.

The remaining list of contraindications includes the major items about which differences of opinion exist. Kirby rates the mild jaundice frequently seen in malarial patients as of small importance, while Osborne, on the other hand, stresses the importance of watching the liver and spleen, which enlarge in from 5 to 10 per cent of patients and of taking frequent icterus indices and van den Bergh tests. Wile and Mundt (1941) report rupture of the spleen. The importance of kidney failure is emphasized by the attention which is paid

to frequent blood urea estimations. Rapidly progressive neurosyphilis and in particular so-called galloping paresis is usually made rapidly worse by malaria as, indeed by most other forms of treatment. While the early tabetic may respond favorably the advanced case is subjected to grave risks quite out of proportion to the probability of improvement.

The Technic of Malarial Therapy

The Organism—Type Source Choice Preservation, and So Forth.—*Plasmodium vivax* the organism responsible for tertian malaria, is the one usually employed in the malarial treatment of neurosyphilis. Quartan malaria (*Plasmodium malariae*) may be used in Negro patients in certain patients immune to tertian infection or in cases where a milder malarial disease is desirable (certain debilitated persons) (Boyd 1934 Branche 1934 Young *et al.* 1940 Fong 1940 Kroll 1940 and others) Ape malaria (*P knowlesi*) has not been widely used (Ciuca *et al* 1937 Milam and Kusch, 1938)

When mosquito-borne organisms are used, the sexual phase of the life cycle is introduced into the situation, whereas if the infection is transmitted by an old strain that has passed exclusively from man to man by inoculation, there is a tendency for the sexual phase to die out, leaving a pure asexual strain which produces a milder and more uniform course and less tendency to relapse after quinine.

Opinions differ somewhat on this point. Rudolf, for example, reports on strains carried in the British hospitals for as long as three and four years with the continued appearance of sexual forms after more than seventy passages. Kopeloff, Blackman, and McGinn have reported on two American strains which became completely asexual after two and one-half years of continuous use in the hospitals of New York State.

It thus appears that the use of a well-established and biologically adapted strain of organism such as can usually only be obtained through continuously functioning institutional sources, is an important asset in the malarial therapy of neurosyphilis and an additional reason for its institutional control. It would seem almost unnecessary to issue the warning that haphazard inoculation from individuals whose strain of organism has not at least been examined as a preliminary or who have been in the tropics and may be the bearers of the malignant estivo-autumnal type should not be practiced. In all cases where a strain is being carried, a properly equipped laboratory should periodically check the characteristics of the organism.

Mosquito transmission is in general, therefore, not desirable though there has been some hope that it might contribute to the problem of maintaining a reservoir for infection where relatively few malarial treatments are given on a service This question is discussed by Rudolf, Gerstmann, Steiner and others.

An important aspect of mosquito transmission concerns the fear which has existed that the establishment of centers for malarial treatment would be in effect that of establishing centers for the dissemination of malaria to the surrounding population. Screening of patients should be practiced during the summer months and the British Board of Control, for example some of whose centers are in regions in which Anopheles is prevalent, insists on strict observance of this rule. A weekly search of the patients rooms is made and patients in well-lighted rooms are allowed to be around without net protection during the daytime inasmuch as the insects bite only at night. While in temperate climate there is less concern about accidental transmission of malaria, Mayne and Young, working in South Carolina, insist vigorously that wards and rooms must be screened, and cite European epidemics resulting from carelessness in this regard.

Malarial blood for inoculation purposes may be transferred from one patient to another by the addition of an equal quantity of 0.5 per cent sodium citrate solution or following defibrination by a glass rod (five minutes stirring) If kept against the person of the messenger to keep it warm it may be sent for considerable distances. Frozen, defibrinated blood has been sent by mail over considerable distances Mayne and Young describe two methods as follows (1) The vials of blood are packed in rubber finger-cots wrapped in gauze and then packed securely in crushed ice in a wide-mouthed vacuum

bottle The bottle is then placed in a specially made shock absorbing card board container The main objection to this method has been the breakage of some containers despite all possible care in packing (2) A less expensive method and one that appears to be quite satisfactory makes use of the Army Medical School water shipping containers These consist of an inside water tight metal screw-top tube 2 inches in diameter and 8 inches long and an outside cardboard screw top mailing tube. The vials are wrapped as above and packed tightly in crushed ice in the inside metal container Successful shipments have been made to great distances in this country These authors defibrinate the blood by shaking with glass beads or anticoagulants (2.5 per cent sodium citrate, 70 cc. to 500 cc. of blood) This may be put up in 5 cc. vials for use or shipment. Stored at 40° F the plasmodium is viable up to 14 days. At room temperature, virulence is retained for from twelve to twenty four hours, but decreases considerably in the longer period. With defibrination and refrigeration in Ringer's solution diluted with donor's inactivated serum sixty to sixty-two hours is the limit (Gerstmann) A virulence retained for forty-eight to seventy four hours is possible with Gerstmann's blood agar method (Rudolf) Kauders's method mixes the blood with Merck's pure gelatin (2 cc. in 10 cc.) with solidification Before use it is melted at 28° C

Inoculation Methods.—Subcutaneous inoculation is preferred by most recent authorities. Intramuscular inoculation is the equivalent of subcutaneous inoculation. Wagner-Jauregg gives subcutaneous preference over intravenous inoculation which he believes leads to quotidian or daily chills. Gerstmann recommends 1 to 4 cc., and Graff 3 to 5 cc Wagner-Jauregg believes that larger inoculations also tend to bring on the quotidian type of reaction. The site of inoculation is unimportant, but Gerstmann, in addition to subcutaneous injections, rubs in a few drops on a scarified area of the arm Intravenous in oculation as used by Gerstmann in doses of 0.5 to 2 cc., and Driver Gammel, and Karnosh have used up to 8 cc. The shortened incubation period is not necessarily an advantage even in rapidly progressive cases. Intracutaneous inoculation, while lengthening the incubation period gives a higher proportion of tertian fever Intraspinal inoculation leads to a high proportion of grave complications (Benedek-Steiner)

Incubation.—For subcutaneous inoculation Rudolf gives 38 to 46 per cent, showing the first clear-cut temperature rise within ten days 41 to 46 per cent in eleven to twenty days and 8 to 10 per cent in from twenty-one to thirty days. The first rise in temperature is not necessarily malarial Plasmodia tend to appear in the blood about the time of the first actual malarial attack. The incubation period for intravenously inoculated quartan malaria (U S. Marine Hospital strain, Charleston, S. C strain) is an average of 15 4 days (ranging from 8 to 28 days) for white patients, and 19.5 days (2 to 65 days) for colored patients (Kroll, 1940)

Malarial Immunity Abortive Cases, and Reactivation.—Immunity t insect-borne and inoculation malaria undoubtedly exists, but is uncommon. Plasmodia may be present in considerable numbers in the blood and the patient may show the clinical improvement characteristic of malarial stage without having been through the normal course of chills and fever Brustch, for example, reports such case with physical and mental improvement and serological return to normal. As rule, immunity t malaria, even in malarious populations, is comparatively slight, but inoculation failures as high as 5 in number have been reported Gerstmann believes second inoculation attacks to be milder than the first (Rudolf, p 67) There is tendency to spontaneous cessation of the fever in second attacks When the same strain is used in second inoculation, parasites may appear in the blood but the percentage incidence of pyrexia with various authors

varies from 0 to 100 per cent. The virulence of a strain of inoculation malaria does not appear to change materially and is certainly not increased by repeated passage through man. The Vienna strain has undergone little or no alteration, Yorke and MacFie found no alteration in forty passages during three years. O'Leary has observed no accentuation, and some strains have even been reported as becoming attenuated.

Failure of Inoculation.—Failure of inoculation is not always due t immunity If the donor has been receiving antimalarial treatment either with quinine or the arsphenamines, the inoculation is apt to fail, and the same is true of the recipient. Bismuth should also be thought of A hot syringe or antiseptic on the glassware or apparatus will cause failure. Rudolf believes that hemolysis of the blood is an unfavorable circumstance. In reinoculations new strain of parasite should be used.

Activation.—I unsatisfactory cases an effort may be made to activate the malaria by injections of sodium nucleinat after the method of Schlesinger and Kogerer or of milk intramuscularly (2 to 10 cc.) or of typhoid vaccine, method not free from danger inasmuch as we have seen fatal collapse without rise of temperature occur following typhoid vaccine in the incubation stage of quartan malaria. This method may also be used to give the patient the benefit of nonspecific proteins during the incubation period but is seldom practiced.

Onset and F brile Reaction.—The phenomena attendant on the incubation and course of malarial pyrexia have been closely studied by Rudolf. Prepyrexial rises of temperature during the inoculation period may occur in paretics, or the temperature may be normal or subnormal *It should be taken every four hours throughout the entire course from inoculation to the termination of quinine* Occasional slight improvement in the mental condition of the patient may appear in the incubation period. Before the onset of the typical attack the patient feels out of sorts with headache and neuralgic pains, and when the rigor develops usually looks profoundly ill, the lips and nails cyanosed and the extremities cold. The violence of the chill is sometimes astonishing and the duration varies from few minutes to two hours or more, veraging less than an hour While the patient is still shivering, the temperature begins to rise the patient is more comfortable, but presently the skin becomes dry the face flushed, and the head throbs. Marked thirst develops and the temperature reaches its maximum followed by sudden decline in tertian cases (persistent high fever in estivo-autumnal contaminations) and profuse sweating occurs Marked variations in individual cases occur The temperature does not usually reach its maximum with the first attack and there may be one or more milder and somewhat irregular rises before the fever settles out the typical tertian swing Large rises on one may be succeeded by small rises on the next, or a typical quotidian form may be carried throughout Wagner-Jauregg believes this daily rise t be too exhausting and that such cases should be terminated after short course when their character is clearly defined The use of bismuth preparations, especially thiobismol, to temporarily suppress the malarial chills has been previously mentioned (Cole, *et al* Schwartz.) I typical benign tertian fever the pyrexia is short, the temperature during the interval sometimes subnormal, and the succeeding chill may occasionally be delayed by twenty-four hours

Temperature should be taken every thirty minutes to an hour during the febrile stage.

Management and Complications.—The recognized complications of malarial therapy are enumerated in Fig 154 The inoculation problems have been considered If the patient is robust, the quotidian type of fever may be well borne, but if it is not, a single dose of 3 to 4 grains (0.2–0.3 Gm) of quinine as recommended by Wagner-Jauregg or of bismuth thioglycollate (0.2 Gm of the salt intramuscularly one dose only) will give a brief remission of two or three days after which a milder form is likely to reestablish itself Quotidian attacks can be avoided by subcutaneous injection of small doses and a donor of a different blood group (Wagner-Jauregg) The beginning of the adequate pyrexial range is at 101 F and a temperature of 106° F is the maximum for safety at which point cold sponges or a pack should be employed to bring down the temperature. When the rectal temperature falls to 102° F., the antipyrexial measures may be discontinued but the effect is usually only temporary and the hydrotherapy must be repeated Rudolf gives a serviceable rule for safety limits—"the three sixes, 106° F., 100 and 60 " representing temperature, pulse and respiration respectively

Blood pressure should be taken with the temperature during the attack, and daily between paroxysms. If it falls below 80 mm. systolic the siege should be terminated. O'Leary and Driver Gammel and Kerneck and Paige Bickloff and Osborne believe that the siege should be immediately stopped if the blood urea rises above 75 mg. per cent. This may occur without recognizable abnormality in the urine.

Blood and urine should be examined three times weekly and a rapidly progressing anemia calls for cessation of the paroxysms. Albuminuria usually develops toward the end of the siege

Fig. 134

COMPLICATIONS IN MALARIAL THERAPY

1. Neurological and Psychic.
   Delirium, hallucinosis, excitement, exaggerated or appearing for the first time with onset of fever or during the period of incubation. Depression and attempted suicide. Safeguard the patient. Focal symptoms from nervous system, paralysis, convulsions, apoplectiform seizures, crises, lancinating pains.
2. Cardiovascular.
   Myocardial collapse
   Falling blood pressure below 75 mm. systolic the danger point.
      Daily observation.
   Transient benign edema.
   Tachycardia, 160 upper limit of safety
3. Pulmonary
   Bronchitis, bronchopneumonia, lobar pneumonia.
   Lighting up of latent or active tuberculosis.
   Edema secondary to cardiac failure
4. Nephritic.
   Rising blood urea (75 mg. per cent upper limit of safety)
   Nephritis.
   Cystitis, ascending urinary tract infection.
5. Liver and spleen.
   Hepatic injury enlargement, rising icterus index (take twice weekly), jaundice
   Splenic enlargement and (rarely) rupture
6. Gastro-intestinal.
   Uncontrollable diarrhea.
   Melena.
7. Hematogenous.
   Progressive severe anemia. Blood count three times weekly
   Fall below 2,000,000 red blood cells dangerous.
8. Malaria per se.
   Inoculation with estivo-autumnal strain of Plasmodium.
   Daily chills instead of alternate days (tertian vs. quotidian type).
   Hyperpyrexia.
   Quinine idiosyncrasy
   Recurrence of malarial infection (usually in mosquito-infected patients—Davidson)
   Prostration terminating in coma (loss of strength between paroxysms of fever first warning
9. Herpes.
10. General.
   Lighting up of other infections, particularly focal.

and glycosuria may be present but is usually without significance. American observers emphasize hepatic injury though Kirby states that the mild jaundice that complicates a number of cases is without significance. Paige, Bickloff and Osborne found marked enlargement of the liver and spleen in 5 to 10 per cent of cases. The icterus index should be taken once or twice a week and readings above 40 call for termination. Red blood cell counts below 2,000,000 require quinine (see p. 343). Rudolf, however rates skin jaundice as a serious sign (conjunctival less significant), though Gerstmann minimizes it. Jaundice without parasites in the blood stream and without fever has occurred and has cleared up under quinine. Splenic enlargement may lead to rupture

i restless or overactive patients, ho should be kept specially quiet. Smear examinations of the blood for parasites re considered by some observers as daily necessity and marked sudden increase in number of parasites as warning for terminating the siege

Pulmonary Complications.—This constitutes an important group rated by Hinde and Blalock as responsible for 11 per cent of deaths after fever therapy The complications may be of three types Edema or pulmonary congestion secondary to cardiac insufficiency; bronchitis, bronchopneumonia, or lobar pneumonia, and focal lighting-up of pulmonary infections already present, including tuberculosis. Rudolf considers pulmonary embarrassment in the ordinary course of treatment, represented by respiratory rat of 60, as an indication for immediate termination of the siege. A wet lung should be interpreted in terms of the heart. Definit localizing signs call for termination of the attack, usually however too lat to void the complication. On tw occasions w have seen apical tuberculosis flared up by fever therapy in one of them the condition previously unrecognized. While the milder courses of treatment given at Vienna have led Gerstmann and others t disregard pulmonary tuberculosis as a complication and, in fact, have enabled them t show instances of satisfactory therapeutic results in such cases, even with improvement of the t berculosis, such latitude is not advisable in general or particularly in America practice ith its tendency to longer pyrexial sieges.

Other Focal Infections.—Arthritis may flare up under malarial therapy and under forms of fever therapy but this is not necessary contraindication. I cases of tabes, however the presence of pyelitis and pyelonephritis is grave contraindication to malarial therapy and Moore has *observed t deaths in a small series from this cause.*

Renal Complications.—These are uncommon though the majority of malarial patients show some albumin nd casts toward the end of the pyrexial siege. Chronic nephritics, however, are t be regarded as ineligible for malarial therapy both because of the kidneys and the heart status of such patients.

Complications in the Nervous System.—These constit te i all probability the largest and most important group. Seizures of various types are quite common in malarial therapy nd are not necessarily t be attributed to the treatment. Steiner Kirby and Rudolf regard them as serious. Steiner believes, however that they may have therapeutic shock significance. Rudolf points out that they may be followed promptly by secondary bronchopneumonia. The poplectiform seizures may leave residual paralyses or may follow the relatively benign course of the paretic epileptiform ttacks.

Excited paretic patients very frequently go int delirium with hallucinosis, extreme excitement and mania hich requires restraint but may subside bet een paroxysms and in any case usually disappears promptly toward the close of the malarial siege or shortly thereaft I fact, it is the initially excited cases hich have the best all-around prognosi Depression with suicidal tendencies may be serious and must be closely watched.

Collapse and Myocardial Failure.—This grave group of complication may present either sudden rapidly progressive drop in strength, as emphasized by Rudolf the symptom continuing bet een the pyrexial attacks rather than during the ttacks; or it may take the form of typical myocardial collapse with rising pulse rat edema, accumulation of fl id in the lungs, and enlargement of the heart or it may present the collapse picture with pallor grayness and cyanosis, and the Hippocratic facies. The anticipated strain on the cardiovascular mechanism is evidenced by the frequent practice of digitalizing patients or giving strophanthus more or less routinely during the incubation period If signs of cardiac eakness ppear the siege should be stopped t once Obese patients are placed in the contraindicated group by most observers, because of their fatty hearts

Kirby rates the transient edema observed in some patients, however unimportant

Arteriosclerotics are of course, subject to apoplectiform attacks and are placed in the contraindicated group

Gastro-intestinal Reactions.—Obstinate vomiting may occur but is unusual in benign tertian malaria, though not uncommon in the estivo-autumnal type. There have, however been number of reports of severe diarrhea (Kihn) and intestinal hemorrhage, grave complication hich may terminate fatally

Quinine Idiosyncrasy—This important though not common complication should really be detected before treatment is begun by the administration of small test dose of quinine. The recognized symptoms of the idiosyncrasy include severe nausea, vomiting or diarrhea; skin eruption, usually scarlatiniform or urticarial, ringing in the ears, dizziness and deafness; impairment of vision dyspnea asthma, and hemorrhages Stitt describes the skin test for idiosyncrasy employing 1 t 10 neutral solution of quinine rubbed int scarified area on the forearm, with a control of normal serum Rudolf reports the successful use of Stitt desensitization procedure hich consists of giving ½ grain (6 mg.) quinine ith 5 grains (0 3 Gm.) sodium bicarbonate

followed an hour and a half later by 1 gram of quinine with an equal amount of sodium bicarbonate.

Recurrence of the Malarial Infection.—This is rarely observed in the benign inoculation types employing blood transmitted from patient to patient.

Management of the Average Patient During the Siege.—The patient should be kept in bed during the febrile period. The temperature should be taken hourly. The blood chlorides should be maintained by a daily ingestion of 6 Gm., with abundant fluid, to replace the loss by sweating. Wile and Mundt (1941) emphasize the danger of chill with low temperature and unusually high pulse and respiratory rate and fever which remains for eight hours after the normal chill peak. Mild icterus is less important, but severe icterus with index above 50, red cell count below 2,000,000, progressive rapid anemia with cessation of chills and profuse diarrhea with vomiting and dehydration constitute serious signs. For peripheral circulatory collapse, transfusion is advocated and Pracy (1943) reports the value of blood plasma in combatting shock which though advocated for physically induced fever should be applicable to malaria. Gerstmann recommends tincture of strophanthus, 10 minims, at the height of each attack, and digitalis, powdered, 1½ grains, may be given twice daily as a preparation in patients in whom cardiac indications exist. Amidopyrine gives relief for the headache if not contraindicated, and sodium bicarbonate may be used for the nausea. Rudolf recommends sugar solution by mouth every two and one half hours, and states that patients feel sustained by it. As sedatives in marked excitement, morphine and hyoscine may be used, and the more powerful cyclobarbital derivatives may be used for the delirium. The dose must be considerably larger than the average. Fluids are forced, the diet should be light during the paroxysms, and cold packs or the administration of a single 2-grain dose of quinine controls the hyperpyrexia and the frequency of the attacks, in stormy cases.

Optimum Fever Levels.—According to the Subcommittee on Fever Therapy of the Cooperative Clinical Group (1940) the highest percentage of clinical remissions was obtained in patients treated with an average of sixty-nine hours of fever above 101° F (38.3° C.), of which total fever time 70 per cent was at a level above 105° F (40.6° C.) with a maximum temperature of 106.9° F (41.6° C.). Equally good results were obtained in patients treated with an average of forty-four hours of fever above 101° F (38.3° C.), of which total time 57 per cent was above 106° F (41.0° C.) with a maximum temperature 107° F (41.7° C.). They were of the opinion that fever administered at levels above 106.7° F (41.5° C.) introduces unnecessary hazards. On the other hand, Kopp and Solomon (1939) found from their 163 paretic patients to whom malaria was given, the amount of fever received at temperature levels of 104°, 105°, 106° F and above did not make any significant statistical difference in the clinical results obtained. The best clinical results were obtained when more than 150 hours over 100° F were experienced.

Length and Termination of the Siege.—American and European practice seem to differ on this point. Wagner-Jauregg's most recent writings advocate two mild siegs of malaria in preference to one intense one, and Viennese practice has rarely exceeded eight or ten fever paroxysms in any one session. On the other hand, American malarial therapists employ twelve to eighteen paroxysms. The general condition of the patient and the end to be attained must be considered in each case.

The termination of the malarial siege is accomplished as a rule by the administration of quinine. A number of dosage systems are in existence. Caccial, quoted by Rudolf, found that the smallest number of relapses (15 per cent) occurred in cases who were given 23 to 30 grains of quinine every day for from seven to ten days. The dose required varies somewhat with the strain. It is rarely necessary to give the drug otherwise than by mouth; the sulphate or bisulphate is satisfactorily dispensed in capsule or in solution in a large amount of fluid. Some observers recommend a preliminary cathartic. Typical dosage scales are the following: 10 grains (0.6 Gm.) of the bisulphate twice a day for three days, followed by the same dose once a day for fourteen days, a total of 200 grains (12 Gm.) (Rudolf). Five Gm. of the sulphate in seven days, using 0.5 Gm. twice a day for the first three days (Steiner). 10 grains three times a day; 10 grains quinine in seventeen days, using 0.5 Gm. twice a day the first three days, and 0.5 Gm. once a day the remaining fourteen days (Gerstmann). Mahlens and Kirschbaum employ a broken-dosage system of 1 Gm. in seven to three days with six or seven quinine-free days between, to a total of 15 or 16 Gm. The dihydrochloride, 0.5 Gm. once or twice daily intravenously may be used under special circumstances.

Antimalarial Substitutes for Quinine.—Various synthetic substitutes for quinine have been proposed. Atabrine di-hydrochloride (dose 0.1 Gm. 3 times daily after meals for five days) is the most acceptable so far. Totaquine and plasmochin may be used but the latter with atabrine, never.

The present emergency has curtailed the use of quinine or even atabrine di-hydrochloride with the result that drugs having some antimalarial action are being examined. Bismuth thio-

glycollate has been suggested. Neoarsphenamine was evaluated from the antimalarial standpoint years ago and found ineffective. Goldman (1938) and Young and McLendon (1939) have tested mapharsen from this standpoint, the former with enthusiastic approval, the latter without success. The latter authors took pains to control their use of arsenoxide and tryparsamide for the termination of quartan malaria; reexamination of blood smears as long as twenty-two weeks after the completion of the mapharsen course showed all of their patients to be asymptomatic malarial carriers. The failure of tryparsamide as an antimalarial agent was demonstrated in the same way. The sulfonamides have been shown to have mild antimalarial action (Coggeshall *et al.*, 1941, Rogers, 1941) but Gibbs (1940) rates them as ineffective. In general it is wiser to employ other method of fever therapy than malaria during the extreme scarcity of quinine.

Postmalarial Treatment and Treatment Combinations.—As O'Leary well points out, induced malaria is not an exclusive form of treatment. Viennese practice has followed the malarial course by neoarsphenamine, 0.3, 0.45, and 4 injections of 0.6 Gm. at weekly intervals (Wagner-Jauregg). There were, however, early differences of opinion in regard to postmalarial arsenical therapy. Gerstmann and Nonne believed that it was unimportant. Dattner (quoted by Rudolf) found 25 per cent of general paralytics treated with malaria alone return to their previous occupations, *whereas 40 per cent of those treated with malaria and arsphenamine did so.* The London County Mental Hospitals' figures gave 33.6 for the first group and 41.7 for the second. O'Leary and Goeckerman who at first opposed, now advocate, postmalarial arsphenamine therapy. Osborne advises at least two or three courses of arsphenamine and bismuth. Kanders takes a similar position.

Particular interest attaches, of course, to the increasing practice of employing tryparsamide following malarial therapy. On this practice a favorable opinion is definitely crystallizing, reinforced, especially, by such painstaking studies as those of Hinds and Blalock and Poole. Methods and results are discussed under Combination Therapy.

Constitutional Gains Following Malarial Therapy.—These are often striking and, according to Wagner-Jauregg, more likely to follow the shorter and milder courses, which he recommends (8 to 10 chills). So striking is the gain in weight and well-being in some patients that it has been spoken of as "resurrection." This gain in physical well-being may take place even without any corresponding mental improvement.

General Principles of Postmalarial Therapy.—The general principles applicable to this question of postmalarial therapy are essentially these. The earlier in the course of a syphilitic infection or the more clearly other evidences of syphilitic involvement besides the cerebral phase present themselves, the more essential is painstaking and intelligent postmalarial treatment with the arsenicals, mercury and bismuth. The patient's syphilitic infection should be treated as a whole; the individual indications should be followed, as in the use of intraspinal therapy, for specific symptoms of low tabes or for primary optic atrophy concurrently present with the paresis; and the ability of malaria to induce allergic relapse, to stir up without silencing both cutaneous and visceral processes, and to injure the cardiovascular system (Wagner-Jauregg) must be borne in mind as a proper justification for general antisyphilitic treatment following inoculation malaria. The amount and kind of the treatment applied will depend upon the indications in the particular case and should, generally speaking, include not only arsphenamine but heavy metal therapy.

The repetition of the malarial siege may be attempted where the results of the first session were unsatisfactory and the condition of the patient warrants. Inasmuch as a tendency toward, though not an absolute degree of immunity is established by the first infection, it is desirable, if possible, to use a different strain of *Plasmodium vivax* for the second inoculation or resort to quartan malaria. A single failure to reinoculate should not necessarily discourage a third, fourth, or even fifth attempt, but the necessity for reinoculation is diminishing with the improvement of non-specific methods for in-

ducing fever and the collateral use of tryparsamide. The outlook for successful reinoculation increases with lapse of time since the first siege.

Mortality of Malarial Therapy—In dealing with a condition such as general paralysis, which has a high mortality of its own, it is extremely difficult to interpret the mortality situation for any form of treatment as such. None the less, we have made the attempt for the mortality issue is after all, one of the most critical in the estimation of malaria as a therapeutic procedure. In Fig 155 which represents in general the routine initiated application of

Fig 155

RESULTS IN MALARIAL THERAPY

Deaths occurring during the malarial treatment or as a direct result of it are marked direct. Further figures concerning the mortality of malaria *per se* are those of O'Leary 1 per cent; Cole, 0.5 per cent; Osborne, 2 per cent. Osborne quotes O'Leary as stating that he has not had a malarial death in his last 200 cases. The studies of Gerstmann from Wagner-Jauregg clinic and of O'Leary are especially valuable in that their figures are based on cases followed from at least two to as long as seven and one-half years after malarial treatment.

Percentages do not total exactly 100 because of decimal losses in refiguring to the table headings from the publications. In some cases the discrepancies are the authors.

malaria to the treatment of general paresis, the wide range must be apparent, and an average can be no more than the merest approximation. It is interesting that the Cooperative Clinical Group's Subcommittee on Fever Therapy (1940) found the crude death rate from malaria to be 13 per cent. Deaths occurring between inoculation and the onset of the fever should not be regarded as malarial, at least if no plasmodia are present in the blood. Deaths during the malarial siege are generally accepted as due to the treatment. The crux comes in the postmalarial deaths, in which the reduced resistance of the patient to intercurrent infections begins to take its toll. In fairness it seems to us that

many of these deaths must be attributed to the form of treatment, though there is a distinct disposition on the part of some authors to minimize or disregard them Rudolf's excellent analysis of deaths before and after onset shows the importance of pneumonia, cerebral accidents, progressive weakness and cardiac failure before the first febrile attack, and the same element after the siege The argument that the mortality of paresis is enormous at best, and *that therefore the smaller comparative malarial mortality is of no significance*, impresses us as specious when there exists, as in this case, a choice of a method like tryparsamide with lower mortality less tax on the resistance of the individual, and *in many cases outright constitutional tonic effects.* Wile and Mundt (1942) found a mortality rate of 2.8 per cent (29 of 1026 patients) Although only 35 per cent of their patients had paresis, 60 per cent of the fatalities occurred among them. The figures of Kryle (0.98 per cent) and the more recent statements of Osborne, Cole, Driver *et al.* and O'Leary and associates (CCG 1940) and Wile and Mundt (1942) are representative of malarial therapy under the best conditions of selection and in early often asymptomatic cases, so that they are not properly comparable with those obtained in institutions for the insane. They are, however the figures toward which we should strive by the increasingly early application of malarial therapy on proper indications, in the course of the individual case

OTHER INFECTION PRODUCING METHODS OF TREATMENT IN NEUROSYPHILIS

The improvement of psychoses through intercurrent febrile infections is a matter of long standing observation, far antedating the introduction of inoculation therapy and, in fact, it was these scattered observations which led Wagner-Jauregg to put malarial therapy finally to the test. One of us (JHS) has observed striking improvement in a paretic patient following an extensive erysipelas covering the entire back. In another patient, now well and active, a severe pyelonephritis with high fever lasting for several weeks, initiated an improvement which was consolidated by the use of tryparsamide Recurrent fever induced by strains of the African spirochete, *Spirochaeta duttoni*, has achieved some popularity in Europe following the introductory work of Plaut and Steiner This organism can be carried in the laboratory in mice for inoculation purposes and produces typical relapsing fever in which the intervals between the pyrexial sieges are longer than in malarial therapy If mouse blood is used for inoculation, care must be taken that no other pathogenic organisms are present. The incubation period averages four to five days, the infection may persist long after the final febrile seizure, and the cerebrospinal fluid is invaded in the course of the disease. Recurrent fever has a number of disadvantages, including its erratic and prolonged course, the fact that there is no means of terminating it short of the spontaneous recovery arsphenamine being ineffective for the purpose. Reinoculation is also impossible, but natural immunity is rare. The complications in general are somewhat less severe than those of malaria, and the therapeutic results, to judge by Steiner most recent summary less good than those of malaria, in the majority of cases. The method, therefore as matters stand today does not seem likely to achieve any wide popularity

As an alternate to malarial therapy Solomon, Berk, Theiler and Clay investigated sodoku, which is the Japanese name for rat-bite fever *Spirochaeta morsus-muris* can be carried as a laboratory strain in guinea-pigs, but the fever produced by it in man, while very satisfactory in some cases, is erratic and inadequate in others, and the method is at best a poor second to malaria, unlikely to achieve widespread adoption The fever is readily terminated with arsphenamine and the constitutional symptoms are as a rule very mild

NONSPECIFIC PROTEIN IN THE FEVER THERAPY OF NEUROSYPHILIS

Typhoid Vaccine —The induction of fever by the use of typhoid or mixed typhoid-paratyphoid vaccine was among the earlier ones studied by Wagner Jauregg It presents certain definite advantages, including the fact that no *strain of* living organisms need be carried the patient is not infected with

any disease requiring separate treatment, the temperature responses by a satisfactory technic are adequate the reactions fewer and the method materially less dangerous than an inoculation therapy On the other hand it has certain disadvantages, including a rapidly developing immunity on the part of the patient to the proteins of the introduced bacteria, and a consequent somewhat erratic behavior on the part of the fever including the necessity for enormous doses to obtain satisfactory pyrexial peaks. This objection can, however be overcome. As the use of induced malaria becomes more difficult because of the scarcity of quinine, typhoid vaccine because of its accessibility and controllability especially for the isolated case may become more popular The technic and care of patients are somewhat less exacting but technical detail is nonetheless essential, particularly with regard to the timing of the injections and their intravenous, not paravenous or subcutaneous, administration. Unsatisfactory fever levels result from inexperience or the use of interne service without proper supervision. Fever levels in refractory cases can be raised by hot drinks and blanketing and the temptation to overdosage should be resisted.

So far as comparisons with malarial therapy are concerned, they are few for comparatively few of the patients treated by this method in various series seem to have been adequately followed. O'Leary rates it as a useful method of treatment with about 15 per cent fewer complete remissions than malarial therapy but well adapted to use as an adjunct where malaria is contraindicated, has failed due to native or acquired immunity or where a malarial strain cannot be carried and only an occasional case is to be treated. Kemp and Stokes, following the original American study of Knode, Hall, and Gerty used this method of treatment in resistant neurosyphilis in general, and found it fairly effective, very well tolerated, and susceptible of repetition in successive courses. The necessity for enormous doses, as high as 4000 million organisms intravenously is annoying and may sometimes produce shock. Nelson devised the plan of giving two daily injections of the vaccine the first ranging from 25 to 50 million organisms, sufficient to produce slight fever and the second administered two to three hours later at the height of the fever induced by the first injection, ranging from 25 to 60 million organisms. By the use of doses from 20 to 300 million in the first and second injections, fever of 105° and 106° F was obtained where only 102.6° F could be obtained by the old single-injection method, using a small dose. His series was too small to judge of clinical or serological results, but our own impressions are very favorable. Driver and Shaw have reported on 21 cases with pyrexial curves fully equal to anything obtainable with malaria. They regard Nelson's method as an acceptable substitute. Kulchar and Anderson (1937) found typhoid flagellar (H) antigen in divided doses provided a safe, satisfactory method of fever therapy which because of the slight degree of systemic reaction, can be used in the treatment of patients whose physical condition does not permit the use of other forms of nonspecific therapy In a more extended study (118 cases) Kulchar and Card (1941) reaffirmed the value of this form of fever therapy H. A. Solomon and Somkin (1946) have proposed continuous infusion of triple typhoid vaccine suspension as a means of inducing controlled sustained hyperpyrexia.

This method in our experience is applicable to the occasional case and is useful in serologically fast patients and other resistant conditions than neurosyphilis. It is not yet recommended as a substitute where malaria is available. The combination of hyperpyrexia and arsenicals can be very well studied when typhoid-paratyphoid vaccine is used, and there were indications in our series that this combination was more than ordinarily effective.

Other methods of inducing fever by foreign protein in the treatment of neurosyphilis have had comparatively little popularity in this country Dmelcos, a vaccine prepared from the streptobacillus of Ducrey neoaprovitan; Coley's serum pyrifer a B coli derivative yeast suspensions have all been used in addition to tuberculin for the production of therapeutic fever but none has thus far demonstrated distinctive advantages or been followed through a sufficient series to judge of its effectiveness.

Chemical Methods for Inducing Fever.—These have now been practically superseded by the other methods described, and can be referred to in the second edition of this work.

PHYSICAL METHODS OF FEVER INDUCTION

With its famous mechanical know-how and gift for the devising of apparatus, the United States has seen the maximum development of fever induction by mechanical means. In fact, foreign observers have been astonished by the tidal wave of enthusiasm for these technics brought on by the war emergency and have done us the compliment to send their ablest talent to observe our progress. Of mechanically induced fever as the apparatus and technic renders the procedure increasingly safe, controllable and not too uncomfortable for the patient, it may be said that probably the whole future of the use of this agent, elevated body temperature in the treatment of syphilis, will ultimately lie within this field. This, we believe, holds, notwithstanding our present feeling that induced malaria as ordinarily practiced, offers the patient the largest return on the briefest investment of time, trouble, and risk. Of the various available procedures, the same principles should be recognized as were recognizable in the field of fever therapy as a whole decade ago. The methods tend at the start to be esoteric, markedly dependent on adequate institutional set-up and highly specialized equipment which has the tremendous disadvantage, especially when used throughout the wide range of manifestations of the disease, of compelling the concentration of treatment into not always easily accessible centers. On the other hand, as familiarity with the methods and training in its procedure is extended, gradual simplification takes place, and there become available alternative procedures of reasonable safety and effectiveness which are usable under a wide range of circumstances with simpler and less expensive apparatus. The controls placed for example by the Miami Valley Hospital group, on the use of the hypertherm, or air-conditioned cabinet, had a valuable effect in preventing a sudden rise in mortality from mishandling by untrained persons, but such restrictions can hardly be indefinitely continued as wider application, broader medical training and increasingly trained technical personnel develops with use. The allure of the gadget also contributes something to American application of these methods. It is therefore proper to point out at this time that a selection of mechanical temperature-raising procedure is possible, contingent upon circumstances, and availability. The electropyrexial technics, because of their more elaborate equipment and more exacting technic of application, will continue for a time the tool of ultra-experts, but there is no present evidence that their superiority in results is such that they will maintain their place against the competition of the simple air-conditioned cabinet. There will, moreover, particularly under stress of war, be need for methods employable where apparatus and technical specialists are not available, and for such purposes, the bath, the blanket and hot-water bags, and the simple light cradle will be found useful. One of the initial serious draw-backs of a machine that can raise temperature so easily to such unprecedented heights and maintain it at such levels for many hours, is the temptation to overplay the game and to employ far more intensive pyretotherapy than may be proved ultimately either necessary or desirable. There is therefore room for further careful study of what might be called ambulatory technic with less frequent and less elevated sieges of fever. That such methods are usually studied where funds and organization as well as mass of patients are at their lowest rather than their highest, possibly explains the slowness with which their potential value is demonstrated.

One of the great advantages of the induction of high body temperature by mechanical means is its noninterference with intensive chemotherapy. The combination of fever and chemotherapy seems both theoretically and clinically so definitely superior to fever therapy alone and so much more specific than fever induced by another infection or by foreign protein, that the fever-inducing devices which make the best combination with chemotherapy seem likely to hold the field for the future.

It seems likely also, as the result of administrative convenience, that the rapidly increasing importance of pyretotherapy in the treatment of gonorrhea unless replaced by a new drug (penicillin?) will *pari passu*, increase its availability for the treatment of the sister venereal infection, syphilis. This is particularly likely under the pressure of war emergency and may lead ultimately to a condition of centralization of the treatment of venereal disease on a wholesale scale in which large fever-chemotherapy institutes are set up for this purpose alone as in the present Chicago experiment. These will be especially important additions to the treatment facilities of large cities.

BALNEOTHERAPY AS A FEVER INDUCING AGENT

Elevation of temperature by means of the hot bath can be carried out on practically any hospital service with a large tub and a competently trained nurse. The assistance and supervision of the plant and attendants in a physiotherapeutic division is a valuable aid, but where prolonged high temperatures

are to be maintained and chemotherapy simultaneously employed, especially in the management of infectious cases, the venereologic or syphilologic division should assume full responsibility The simplified technic, adapted to ordinary hospital use is summarized from Boak, Warren and Carpenter's contribution below

The experimental background of this method, based on the work of Schamberg and Rule, is discussed in Chapter V Mehrtens and Pouppirt, treated 70 patients, giving 900 baths during period of one and one-half years. The patients ranged in age from seventeen to seventy and included many unpromising risks. While continuous bath equipment is desirable, it is not absolutely necessary Mouth temperatures ranging from 104 to 105° F and even 107° F were obtained by bath of 110° F which was started, for timid patients, at temperature of 105° F The temperature of the bath water was gradually reduced to that of the patient after the desired response was obtained. Temperatures were ordinarily maintained for two hours, sometimes by removing the patient from the bath, wrapping him in hot blankets with hot-water bags, and administering hot liquids by mouth. The authors believe that Hollingsworth poor results were the consequence of insufficiently hot baths and insufficient time at the maximum fever temperature. Patients lose, from 3 to 5 pounds' weight with each bath, which is recovered, under proper dietary management, by the next morning. Most patients end series of fourteen baths with gain of weight. The pulse curve follows normal variations, the blood pressure is reduced in most cases, there were increases of hemoglobin and red cell count occasionally with 2 to 3 per cent increase in reticulocytes. At the lower temperatures the patients were calm and cooperative, at medium temperature (102° 103° F.) very frequently showed signs of restlessness and anxiety and at the higher temperatures became apathetic and later mildly confused. None of these effects was serious. The permeability of the meninges was increased, as shown by the Walter bromide test. Of 11 paretic patients, 2 were able to return to work, 4 showed marked improvement. Marked symptomatic benefit ensued in tabes, particularly in patients with lightning pains, gastric crises, and painful Charcot joints. When given routine antisyphilitic therapy in conjunction with the hot baths, the effects seemed materially improved. Baths may be continued daily for at least six weeks and the patient may still gain in weight and maintain his strength. The studies of Dosmis, *et al.* (1936) and Warren have been previously referred to.

Verbal reports from some of our institutional friends indicate that this method is more feasible and effective than at first appears. It would be desirable to devise methods of controlling weakness, perhaps through the loss of chlorides from sweating One observer mitigated the discomfort of his patients by allowing them to keep one leg, from the knee down, outside the tub.

ELECTRICAL METHODS FOR INDUCING FEVER

Physical.—Two methods have been developed.

The better known of the two methods consists in the passing through the body of the *patient of high-frequency current generated by diathermy apparatus of 4000 to 6000 ma.* capacity Large fenestrated electrodes of special construction are applied to the chest, abdomen and back, the principal problem being to get the necessary amount of current through the patient body without producing burns. In the Cook County Hospital and the Elgin State Hospital, where special technic and facilities were developed, the results were highly satisfactory In addition to the correct application of properly constructed electrodes and sufficiently powerful machine, insulation of the patient ith seven blankets and rubber sheet is necessary The rate of temperature rise in patient depends upon the mass of the patient, current and insulation, and any type can be imitated. Perfect imitations of malarial stage, so far as temperature curve is concerned, can easily be produced. The final temperature of the body overshoots the highest temperature obtained during the operation of the machine, so that it must be cut off before the critical point is reached. Restless and disturbed patients are particularly apt to receive burns, which usually occur around the pelvic girdle, where the body is thinnest. The changes in the blood and body chemistry are those of high fever Neymann (1936) has compiled an excellent table, summarizing the work of all reporters on electropyrexia, with total of 975 cases of dementia paralytica, 260 (27 per cent) *complete remissions, 354 (36 per cent) improved, and 23 dying as the result of treat*ment (2 per cent) Neymann and co-workers tend to minimize the difficulties, which are doubtless minimal under sufficiently expert technical direction. Most of the diathermy cases began to show improvement only after the eighth to the tenth treatment. It is particularly interesting that number of the older cases had been treated with malaria and sodoku without result. Salisbury

and Eichenla b failed t secure results in 17 cases of attempted direct diathermy treatment of the head.

Th second method of producing fever electrically consists in placing the patient in the field of high-frequency oscillating condenser The discovery of the pyrogenic properties of this type of electrical energy as made accidentally in the General Electric Laboratories in Schenectady where Whitney noted that orkmen in the field of high-power short wave radio transmitter developed fever Whitney Carpenter and Page, Carpenter and Boak, and Hinsie, have done preliminary work but the Carpenter Warren group has gone *over completely t the radiant* heat cabinet, giving up the electrical induction of fever There is a marked rise in the local temperature of organs ithin the bodies of experimental animals and Hinsie and Blalock have shown rise of 75 per cent in leukocyte count in the blood. Six months after treatment by thi method.

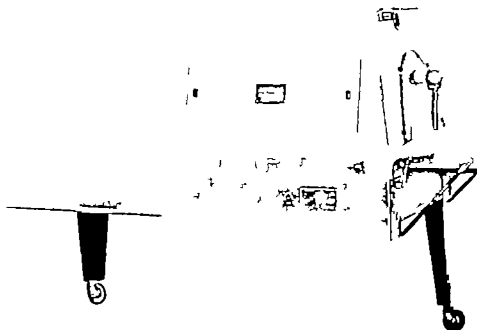

Fig 156 —The hypertherm (closed) (courtesy of Dr H. W Kendell)

17.6 per cent of their patients showed remissions, 33 3 per cent were improved, 38.2 per cent unimproved, and 8 8 per cent dead. The malarial controls gave remissions 19.1 per cent, improved 35.3 per cent, unimproved 30.9 per cent, and dead 14.7 per cent.

Conditioned Air and Radiant Heat Cabinets.—Excellent descriptions and reviews of this type of apparatus, now the most popular means for the mechanical induction of fever have been published by Simpson (1935 1940) Desjardins, Stuhler and Popp (1936) Krusen (1930) Krusen and Elkins (1939) These types of apparatus were the offshoots of attempts to control the arcing and induction of burns by electrical current at points of accumulated sweat The Kettering Hypertherm (Fig 150) utilizes humidified heated

Fig. 157

THE ESSENTIALS OF INTENSIVE PHYSICALLY INDUCED FEVER THERAPY

I. Organization and Personnel.
1. An institutional set up for prolonged sessions, extensive use.
2. A physician in charge who has expert knowledge of every complication and contra-indication.
3. A trained technician or nurse (not less than 4–6 weeks institutional instruction) in constant attendance at the patient's side.
4. For smoothness and comfort for the patient, there must be tact, confidence, consideration and know-how in the attendants.

II. Equipment.
1. Air-conditioned or radiant heat cabinet approved by the Council on Physical Therapy, American Medical Association preferred. Diathermy and other electrical induction methods less safe, more difficult, losing ground. Bath and blankets useful but slow, uncomfortable; may be necessary makeshifts for lower temperatures, shorter sessions.
2. Self-recording electrical rectal thermometer. Mouth axillary and hand-rectal methods makeshift.
3. Blood pressure control.
4. CO_2-oxygen-inhalation equipment (Boothby mask).
5. Antishock equipment (glucose and plasma set, sponge tray, etc.)

III. Patient-Supportive Measures.
1. Instruction, reassurance, comfort (soft mattress, head exposure, body freedom).
2. Adequate preliminary work-up—physical examination and diagnostic survey, functional tests of heart, kidneys, lungs, liver. Blood count, sedimentation rate, urinalysis, electrocardiogram, chest roentgenogram, blood chemistry.
3. Salt replacement—NaCl 8 to 20 Gm. according to fever duration in 3000 to 8000 cc. fluid (iced tea, fruit juices, sweet beverages).
4. Intravenous glucose 5 per cent in 1 per cent salt solution, 1000 cc. if needed.
5. Oxygen with 5 per cent CO_2, inhalation p.r.n.
6. Cold compresses to the head. Light covering of skin surface and prominences.

IV. General Principles.
1. The higher the fever and the longer the session, the greater the risks.
2. The patient must be *observed* (not merely looked at) continuously. Vigilance is of the essence.
3. Contraindications and possible complications should be re-considered with each session, not merely at the outset.
4. *Remember the five 6's*: T 106° P 160, R 60, BP (diastolic under) 60 BUN over 60 (upper limit of blood urea nitrogen). These mark the danger line.

V. Complications. *Death* (vascular collapse shock, heat stroke, cerebral hemorrhage and edema, pulmonary edema, hemorrhage). *Psychic disturbance* (restlessness, dementia). *Convulsions. Headache* during and after. *Nausea and vomiting. Cramps*, abdominal and muscular. *Tetany. Skin*, erythema, herpes, burns (electrical). *Albuminuria.*

VI. Treatment of Complications (Turville and Fetter 1945). *Headache* aspirin. *herpes simplex* compound tincture of benzoin or 5 per cent ammoniated mercury ointment; *local erythema*, protective pads, *nausea and vomiting* 500 cc. 5 per cent glucose in 2 per cent salt solution intravenously followed by 1–2 liters 5 per cent glucose in normal saline solution; *intractable vomiting*, stop. *tetany*, 10 cc. 10 per cent solution calcium gluconate intravenously; O_2–CO inhalation calcium by mouth; *delirium and hysteria*, ¼ grain morphine repeated in two to three hours, reassurance; if persistent, stop; *circulatory collapse* 1–2 liters 5 per cent glucose in normal saline intravenously, small doses epinephrin, caffein sodiobenzoate, or coramine; if not responsive, O_2 inhalation and plasma transfusion. *heat stroke* stop treatment, sprinkle body with warm water ice-water enema 100 to 200 cc. 50 per cent glucose or sucrose solution intravenously; spinal puncture or venesection for *cerebral* or *pulmonary edema* respectively; *convulsions*, sodium amytal intravenously 3.75 to 7.5 grains occasionally hypertonic glucose and lumbar puncture.

"IF IN DOUBT TAKE HIM OUT"

Fig 138.

AMBULATORY FEVER THERAPY

(Exigent, Casual, Substitute)

1 Weekly or semi-weekly sessions.
2. Preferably combined with chemotherapy Give as fever drops toward normal.
3 Aim for six hours over 104 F per daily session, total of fift hours, t 105°
4 Adequate record of each step and finding must be kept.
5 *Easily obtained by cabinet methods.*
6. Other procedure as follows
   (A.) Blanket: 5–10 Gms. salt i 1000–2000 cc. water preceding t hours. Blood pressure, temperature pulse. Wrap in sheet and 2 3 blankets, enclosed in rubber sheet, with hot w ter bags. Force hot sweet drinks; temperature axillary later mouth, q thirty minutes. Electrically wired (waterproofed and insulated!) blankets may be used. Do not wrap. Place above and below Method slow uncomfortable, trying for patient.
   (B.) Blanket and Cradle (after N Epstein) Wrap in bath blankets, large woolen blankets, rubber and canvas sheeting. At start, cradle ("common body frame") with 12 carbon lights is placed over patient. The patient is given no special preparation and is permitted to have breakfast. Long woolen socks are placed upon the feet and legs to the knees. A heavy woolen blanket, a canvas sheet and rubber sheet sufficiently large t cover the entire patient are placed upon the bed. Warmed thin blankets are wrapped around each limb and the trunk of the patient so that no part of the body is uncovered except the face. Seven bath blankets are used. The heavy woolen blanket, the canvas sheet and the rubber sheet are successively brought up and wrapped around the patient. Two more heavy woolen blankets are used, one is placed over the feet and lower half of the body the other is wrapped around the entire body During the treatment the patient may be placed in a semi-sitting position if desired. 100 cc. of hot lemonade (100 F) containing sugar and 0.6 per cent sodium chloride is given at one-half hour intervals. 3–4 liters are given during the treatment. Morphine sulphate gr ¼ nd tropine sulphate, gr $\frac{1}{150}$ are given hypodermically for restlessness and morphine sulphate, gr ¼ may be administered t or three hours later if necessary The oral temperature is taken t least five minutes before hot liquids are given and the pulse is counted at the temple t half hour intervals. The fever is permitted t rise to 40 5° C. (104.9° F) and is maintained between 39 C. (102.2° F) and 40.5° C. (104 9 F.) for six hours. At the conclusion of the febrile period the blankets are removed, a warm alcohol rub and cool drinks are given. The patient requires expert ursing care throughout the period of hyperpyrexia The onset of alarming symptoms such as rise in temperature above 40 5° C. (104.9 F) or of the pulse rate above 150 per minute, tendency toward collapse or the onset of tetany are indications for lowering the temperature or discontinuing the treatment. Loosening the blankets as rule will cause prompt decline in the temperature. Occasionally fanning the body tepid sponges, ice hips by mouth or cold colonic flush must be used t reduce the fever A fall in systolic blood pressure below 80 mm. of mercury should be regarded as sufficient cause t discontinue the treatment. There is an even and gradual rise in oral temperature veraging 0.2° C. per fifteen minutes or 0.8 C. to 1 0 C. per hour. The rectal temperature is 0.3° C–0.5° C higher than the oral temperature A temperature of 39 C. (or 102.2° F) is attained in three t four hours, and 40° C. (or 104 F) i four t five hours. This temperature is then easily maintained for the febrile period. The pulse rarely exceeds 140 per minute and the respirations 28 at the height of the fever The temperature falls t normal in about one hour after conclusion of the treatment. The initial rise in temperature an be greatly accelerated by placing a common lectric body bake over the patient for one to t hours before the rubber sheeting is wrapped round him.
   (C.) Tub (after Bozk, Warren and Carpenter) 2 Gms. salt in 500 cc. water by mouth two hours before and after bath, 2000–4000 cc. fruit juices, tea, t during and after *Bath.* Immerse patient completely p to chin in t b of water t 42° C (107° F) Additional hot ater is added as needed t keep the ater temperature constant t thi level. The w ter should be stirred and mixed, and the temperature of the ter measured at both ends of the tub.

Fig. 148.—Continued.

1. The mouth temperature and pulse are to be measured accurately every five minutes by the clock. When the oral temperature reaches 103° F the patient is to be taken at once from the tub, dried off, wrapped in a dry sheet, and placed on a cot t cool down. Patient can be allowed t walk to the cot, unless dizziness, nausea, or palpitation is present. Duration of session about forty minutes. Note the most critical period is the five-minute period at or near 103° F The temperature will rise rapidly if the patient is left in too long at this level.
2. Blood pressure reading following bath.
3. Take temperature t ice more after patient is out of bath t be certain patient is cooling down.
4. During cooling down process at least t glasses of cold ater (400 cc.) should be ingested, to which salt may be added if water tastes flat.
5. 2 Gms. salt and water to be given one hour after bath.

(D) If the patient feels chilly after the bath, he should be covered as much as necessary for comfort only He may be allowed t sleep for half hour or more, and thereafter may rise and walk about.

(E.) If arsenical therapy is t be used, the injection is given during the cooling off period.

(F) Tub bath procedure may be repeated again after eight hours if desired.

air distributed by fans from a fireproof chamber at the end of the cabinet to the patient lying at rest upon a suitable sponge-rubber or air mattress, completely enclosed under a cabinet cover which can be lifted for adjustments, necessary observation and so forth. Only the head of the patient projects, the neck being enclosed by a sponge rubber collar which is soft, flexible and devoid of constrictive effects The self-recording electrical rectal thermometer is regarded as an essential part of these types of equipment, and fans for cooling the exposed face and head are desirable refinements. The radiant heat cabinet devised by Warren simplifies the equipment by doing away with the air-conditioning and circulating apparatus. It con ists of an essentially similar cabinet, in the top of which are housed five 200-watt Robert Schwartz heating lamps, so arranged that three irradiate the trunk of the patient and two the lower extremities. This type of lamp is chosen because it is a strong emitter of infra-red rays. The lamps are controlled by rheostats, since they deliver more energy than is usually required. Other types of luminous and non luminous heat cabinets have been designed but the prospective purchaser of uch equipment should consult the reports of the Council on Physical Therapy of the American Medical Association which has painstakingly investigated the various available types. While each type of cabinet has its advocates, the evenness and continuity of the fever in the Hypertherm without the necessity at any time for exposing the patient are being stressed, and the relative simplicity efficiency and inexpensiveness of the radiant heat type.

It should be clearly understood that the use of these types of apparatus is not to be regarded as an office procedure at this time that the skill and experience of the medical and technical attendants re of far more importance than the apparatus and that the mere ability to secure the apparatus furnishes no justification whatever for the employment of it in the treatment of disease

Electrically Heated Blankets.—These are rubber-insulated, covered wire-mesh devices similar to electric heating pads which are applied outside of zipper bag completely enclosing the patient. The close confinement is disturbing in proportion t the elevation of temperature sought, as in the case of other blanketing devices, hich limits the usefulness of the method, and thus far no device of this sort has received the pproval of the Council on Physical Therapy (1943)

CHAPTER IX

THE REACTIONS, COMPLICATIONS AND CONTRAINDICATIONS OF TREATMENT FOR SYPHILIS

The Factors in Reaction.—Under the intensive and radically curative régimes made possible by modern syphilological methods no small part of the art of treating syphilis consists, not in the mere administration of doses of this or that, but in the study and prevention of unfavorable reaction, and the minimizing of treatment risks. It is very difficult to escape the tendency to blame the drug exclusively when one encounters a reaction to treatment. The names "arsenic" and "mercury" have been so long associated in our minds with gripes and poisoning that the *post hoc* type of reasoning is inevitable and natural. The tendency must, however be consistently fought by all who wish genuinely to understand the mechanism of treatment reactions. Injurious reaction from faulty preparations is extremely unusual. No small part of the trouble encountered in modern syphilis treatment arises from medical and technical error and from individual and often remediable peculiarities in the patient.

It follows, therefore that the study of the patient's individual reaction to treatment must never be neglected for any system or routine, no matter how authoritative the source. If we decide to push a given method through in the face of contraindications, it should always be with full knowledge of the risks involved and the end to be attained. On the other hand, if we bow too easily to the first indication that the patient is having difficulty with some phases of his treatment, we shall be weak-kneed therapists and have a correspondingly poor aggregate result.

Tracing Reaction Causes.—Because a patient develops jaundice after an arsphenamine has been given or stomatitis after a mercurial, it by no means necessarily follows that the drug is the cause of the reaction. A theory of predisposing as contrasted with exciting causes does excellent service here. Moreover the study of reaction tendencies makes it increasingly clear that all the various drugs employed, but particularly the arsenicals and bismuth, play upon a physical reaction mechanism involving the vascular system, the liver and the kidneys together with the gastro-intestinal tract, in ways which make the effects of combined treatment with two or more drugs often very difficult to interpret. This fact became particularly apparent in the Cooperating Clinic survey of reactions in early syphilis in which it appeared quite definitely that treatment with an arsphenamine alone gave rise to a comparatively trifling number of complications as compared with the effects of combining a heavy metal in the scheme of treatment. The various factors involving a stepping-up of reactivity and a reduction of tolerance are therefore constantly interwoven and make the reacting patient a problem for a high degree of individualization and expert study. Fortunately however there are certain general principles and general measures which have a wide degree of validity in all cases.

The Distinctive Reaction Tendencies Recalled.—Let it be recalled, then that the trivalent arsenicals attack the vascular system and the liver and

through the vascular system the skin. The bone marrow is also more subject to arsenical attack. Pentavalent arsenicals attack the nervous system. The kidney is in general relatively exempt; the gastro-intestinal tract usually only mildly though perhaps disagreeably affected. The heavy metals, because

Fig. 190.

SOME MAJOR AVOIDABLE CAUSES OF REACTION REVIEWED

1. Failure to consider the patient as a whole or to examine in particular for: (a) damage to vital structures; (b) activity of the disease in vital structures; (c) intercurrent disease.
2. "Wassermannism" or "Serologism." Treating for or by the blood test alone.
3. "One system for all," one drug, one size ampule, no weighing of risks against benefits.
4. Failure specifically to consider tolerance in each case.
5. "Taking a crack at it":
   Unfamiliar with the common drugs,
   Or their reactions,
   Or outright contraindications.
6. Experimenting with unfamiliar drugs without previous study.
7. Pamphlet and drug circular syphilology.
8. Arsphenamines without preparatory treatment in syphilis of vital structures, implying:
   Unfamiliarity with therapeutic shock (Herxheimer effect),
   Unfamiliarity with therapeutic paradox ("the fatal cure").
9. Wrong drug for the purpose, e. g., 100 injections × 0.9 Gm. "914" in paresis. Bismuth alone in primary syphilis.
10. Wrong route for the right drug: e. g., bismuth intravenously.
11. "One dose for all." Failure to regard weight, and other standards.
12. The initial overdose.
13. Disregard of cumulative effects, especially heavy metal.
14. Failure to watch the eliminative mechanism: the kidney, the bowel.
15. Rest intervals in early syphilis.
16. Treatment by hearsay.
17. Hurry.
18. Defective drugs or drug containers (a rare cause).
19. Dietary mistakes:
   Full stomach before injection.
   Too much roughage.
   Too much carbohydrate.
   Alcohol.
20. Technical blunders:
   Giving acid "606" for "914."
   Fast injection—"speed shock."
   Improper mixing of neoarsphenamine:
      Imperfect solution.
      Aeration.
      Shaking.
      Standing.
   Failure to pull back on syringe plunger (Fig. 196).
   Injection into inner and lower quadrants (of the buttock).
21. Failure to inquire for, see, or heed warnings of serious reaction, especially from the skin (itching, rash, purpura) before each treatment.

NEVER GIVE A FIRST INJECTION WITHOUT THOUGHT; NEVER GIVE A SECOND WITHOUT KNOWING WHETHER THE FIRST WENT WRONG OR NOT AND WHY

of their mode of introduction, have annoying local effects. They act as depressant protoplasmic poisons instead of tonics, as in the case of the arsphenamines. The gastro-intestinal tract, and particularly the mouth, is the site of many reactive phenomena under heavy-metal therapy. The kidneys in general

Fig. 160.

SOME FUNDAMENTAL FACTS CONCERNING TREATMENT REACTIONS

Based on the major reports in the literature 1920–1943.

1 Some degree of reaction is probably inevitable in effective treatment for syphilis. It is inherent in the composition and metabolism of the drugs.

2. The frequency of complications is influenced greatly by uniformly correct, stable and expert technical preparation and manipulation of drugs, especially in clinics. (Haase and Marshall, Stokes.)

3. All reactivity is increased by the intensive use of heavy metals. With arsphenamine alone, the reactivity is low (38.7 per cent *versus* 56.3 per cent)

4. The patient who has one complication tends to have others.

5. Increasing age of the patient and of the infection influences the incidence of reaction (see p. 306) Dermatitis, jaundice and nitritoids tend to be less frequent in older patients. Gastro-intestinal reactions and pruritus increase in secondary syphilis.

6. The greatest incidence of reaction is between the sixth and the tenth or seventh to fifteenth injection in the arsphenamine series (Cole, Harrison); 75.2 per cent before the tenth, 45 per cent between the first and fifth (Univ of Penna.); with a drop after the twentieth and a rise after the fortieth. A series of from 20 to 40 injections, therefore, brings the patient int a period of minimal rather than maximal reactivity; 5.5 per cent after the twentieth (Univ of Penna.). After the latter figure the risks again increase. Severe reactions may occur early or late, depending on the type of reaction. 87 per cent of crustaceous dermatitis reactions occur less than two months after beginning of treatment (92 per cent follow 1 t 6 arsenical injections) (Waugh and Milovich, 1940) but blood dyscrasias tend to appear late in the course of therapy (Burke 1941)

7 Dosage probably influences the later reactions more than the early ones, grave cutaneous and vascular reactions may follow very small individual and total doses, early and late in treatment, and overdosage leads t many and severe reactions. (Mahrowsky Statistics, Fig 161.)

8. Secondary syphilis, in the aggregate, however is less reactive than primary

9 Early syphilis is less reactive than latent syphilis. (Cole, 15.3 per cent *versus* 19 per cent.)

10. Complications are roughly divisible into major (severe) and minor (mild) as follows: Under major reactions are included aplastic anemia, atrophy of the liver exfoliative dermatitis, jaundice, purpura hemorrhagica, aleukemia hemorrhagica, hemorrhagic encephalopathy severe gastro-intestinal reactions, ocular damage, renal reaction, and death. Under minor reactions are included slight skin eruptions, pruritus, Herxheimer effect, nitritoid reaction, arsenical stomatitis (unassociated with aplastic anemia) For relative frequency see Figs. 161 t 178

11 Continuous treatment causes more minor but no more, if as many major reactions, as the much less effective intermittent treatment.

12. Kidney tolerance is better under continuous tha under intermittent treatment (6.1 *versus* 18.5 per cent reactions) MacF rland showed that the kidney acquires a tolerance of treatment.

13. The aggregate incidence of arsenical reactions is 15.3 per cent of cases (Cole)

14. Arsenical reactions as such are most frequent in ages forty and forty-nine.

15. Of the patients who have had one arsenical complication, nearly two-thirds can cautiously continue treatment. Of those who have had two complications, 25 per cent can continue arsenical treatment (Cole *et al*)

16. Of patients receiving two arsenical treatments, only about 0 per cent were sensitive t both. A change of drug may therefore reduce reaction (For precautions in dermatitis cases see p. 428)

17 Sensitivity to th arsenicals lasts from verage of eight and four-tenths months (Cole 63 cases) t seventeen years (in Burke case)

18. Hemorrhagic encephalopathy affects the young adult nd ha mortality of 30 t 50 per cent. (Cole Harrison, Phelps and Washburn) It causes 50 per cent of treatment death

19. Exfoliativ dermatitis may occur after much or little arsphenamine The factors involved are discussed on pages 216, 253. It causes 23 per cent of deaths.

20. Neoarsphenamine gives rise t more icterus, much or more dermatitis and more severe gastrointestinal reactions than 606. Arsphenamine 606 gives rise t more minor reactions, but only very few more major ones th 914

Fig 160 (Continued)

SOME FUNDAMENTAL FACTS CONCERNING TREATMENT REACTIONS
(Continued)

21 **Sulpharsphenamine** in the United States Navy has nearly as good a reaction record as neoarsphenamine, but this cannot be said of reports from civil practice except when the drug is used in children.

22. **Mapharsen** (an arsenoxide) has an exceptionally low incidence of all types of reaction, especially nitritoid, when used in standard systems of treatment. Under some circumstances it may be tolerated by patients who develop mild reactions to other arsenicals. It is capable however of causing severe reactions and death in intensive systems, from encephalopathy and blood dyscrasias.

23. **Reaction statistics** are much influenced, probably by treatment technic, clinic versus private practice, patient's physical status, diet and nutritional state of the patient, season of the year, patient's nervous state, pregnancy, intercurrent infection, follow-up effort and gradual progress in the perfection of drugs.

are more markedly affected than with the arsenicals, the vascular system less so. The liver, although it is the great toxicity burden-bearer of the body, is definitely less affected by the heavy metals than by the arsenicals. The skin likewise has a relative immunity to heavy metal effect. Mercury and bismuth part company very definitely in reaction-producing qualities, mercury damaging the gastro-intestinal tract and the kidneys, bismuth tending toward the arsphenamines in the greater inclination to affect the vascular system and the liver. It follows thus that in the interpretation of reaction there is a rational tendency to ascribe vascular, hepatic and cutaneous reactions to the arsenical element in treatment and gastro-intestinal (including stomatitis) and renal reaction to the heavy metals. Iodide occupies a curiously nondescript position. Its reactions are mainly the products of gastro-intestinal irritation and of idiosyncratic, quasi-allergic manifestations. The bad taste, the colic and dyspepsia, the acne, coryza are essentially trivial. Only rarely does one meet a reaction to iodide serious enough to cause alarm.

The Morbidity and Mortality of Treatment Reactions.—Knowledge of this field has advanced materially in recent years, although incomplete reporting and differences in statistical interpretation still lead at times to scarcely credible figures. The difference between ambulatory, hospital, and private practice becomes increasingly apparent as one finds himself preponderantly involved in one or the other. Probably the only true reaction statistics are to be obtained from a bed service with patients under constant and long-time control, such as one scarcely obtains outside of isolated communities, penal institutions and with massive arsenotherapy. For practical purposes, however, the general situation is fairly clear and the reactions which escape recording in ambulatory practice tend to be of minor importance. There is, however, much difficulty in distinguishing between avoidable and unavoidable morbidity and mortality. The administration of arsphenamine to a patient with an obvious contraindication may result promptly in death, not from the arsphenamine as such, but from its improper use. Such complications as pneumonia developing when the drug is given at the onset of an acute bronchitis; death from rupture of an aneurysm or from angina pectoris if the treatment is begun without proper preparation; exfoliative dermatitis following a repetition of treatment in a patient who gives obvious warning signs that were overlooked; aplastic anemia and fatal purpura developing under the same circumstances, death from a cerebral accident, if arsphenamine is given in a large dose to a patient with an acute syphilitic involvement of the brain (Herxheimer effect) cannot fairly be laid at the door of the drug. Such treatment reactions are not drug reactions in any proper sense, yet they are only too readily used by antagonists to discredit even the intelligent use of modern method.

(a) **The Statistical Summaries.**—Current knowledge of the incidence of reaction is summarized in a series of Figs. 161 to 172. These at first are fairly representative of present-day American

as is inevitable in ambulatory practice, number of the mild reactions. The incidence of mild reactions as such, for Stokes' Mayo Clinic service was from 22 to 26 per cent for arsphenamine (606) and 2 to 8 per cent for neoarsphenamine. The chief serious reactions are gastro-intestinal, hepatic injuries, and dermatitis, the chief minor reactions, vascular and cutaneous. Recall that these patients were on combined treatment and that there was no hemorrhagic encephalitis and only one fatality in the group. Fig. 102 shows the incidence of reported reactions to Mapharsen. The absence of nitritoid reactions and the scant number of cases of exfoliative dermatitis are noteworthy.

Serious and Fatal Reactions.—Recent studies of the severe and fatal reactions to the arsenicals based on standard systems of therapy have emphasized in addition to hemorrhagic encephalopathy as the chief cause of death from

these compounds (Cologne Commission 1920 and U. S. Navy 1919–1927; Phelps Cooperative Clinical Group, 1933) the cutaneous, hepatic and "shock" reactions as causes of death (Hahn 1941); Stephenson, Chambers and Anderson (1943) (Fig. 103). In the case of intensive (massive) arsenotherapy hemorrhagic encephalopathy is still the outstanding obstacle in the popularization of the "five day" or other foreshortened treatment schemes (Leifer, Chargin, Hyman (1941); Thomas and Wexler (1941) and Thomas, Wexler and Dattner (1942).) Acute yellow atrophy of the liver accounted for 20 of the 45 arsenical deaths in the Johns Hopkins Hospital series (Hahn (1941).) Dermatitis was second, causing 8 of the fatalities. The introduction of mapharsen has materially reduced the incidence of cutaneous reaction (Epstein (1941)) to a

fraction of that caused by other trivalent arsenicals. Although factors involved in the production of arsenical reactions will be discussed later special attention should be paid to the tendency for certain drugs to induce severe or fatal reactions (Cole, Burke (1941))

Mild Reactions to the Trivalent Arsenicals.—These are detailed in Fig 165 Those for the Mayo Clinic probably present the truer picture. Ireland's study from the University of Pennsylvania (left-hand column, Fig 165) shows quite clearly how reports of lesser reactions such as headache, mild diarrhea, fever and subjective complaints fade out of the statistics of an ambulatory service On a service conducted by experienced operators and

technicians under constant experienced control and supervision the nitritoid crisis practically disappears as a significant reaction but the proportion immediately rises, under the pressure hurry and more casual conduct of an ambulatory or dispensary clinic Use of mapharsen, as previously stated, avoids the nitritoid crisis. Gastro-intestinal disturbance rates very much the same in both types of clinic and is one of the abiding annoyances and difficulties of the modern treatment of syphilis, responsible for an unknown amount of disaffection, lapse, and noncooperation on the part of patients.

That in the incidence of mild as contrasted with severe reactions the ambulatory clinic is not necessarily at a disadvantage is indicated by Ireland

to hospitalize patients on whom one expects to carry out intensive methods. To the objection to out-patient statistics occasionally offered, that reacting patients go elsewhere and are never

heard from, we would interpose the personal belief that while this is true of mild reactions, one *hears very promptly in one way or another from every serious reaction for which an ambulatory* service is responsible. This is not true of the practice of the private physician, in our experience, for he may lose his patient, especially if part-pay or semi-indigent, to the hospital in the event of serious trouble without hearing anything further of the case.

Incidence of the Serious Complications—Dermatitis, Jaundice, Encephalopathy, Blood Dyscrasias.—Exfoliative dermatitis is with good reason one of the most dreaded complications of modern antisyphilitic treatment. Figure 167 summarizes an extended experience in which the statistical interpretations must vary somewhat on the basis of degree of severity of the cutaneous reactions. The unusually low incidence of dermatitis due to neoarsphenamine is demonstrated by these data. The striking difference in the incidence of jaundice in various reports is apparent (Fig. 167).

HEPATIC INJURIES "CAUSE" 10 PER CENT OF DEATHS

The epidemic factor involved is discussed on p. 249. *Hemorrhagic encephalopathy* is extremely variable in its onset and the comparatively low incidence of hemorrhagic encephalitis in Stokes' experience may be a matter of good fortune. That two clinics using preponderantly "606" (Cole and Stokes) have so low an incidence of the complication due to the drug, while a few injections of sulpharsphenamine in Cole's clinic yield 4 cases, and in the Navy none, argues for the entirely erratic character of the reaction or its association with special brands of drugs. When neoarsphenamine is employed in standard systems of treatment this reaction is rare. Aplastic anemia, only recently appreciated in this country, together with its purpuric and hemorrhagic accompaniments as a phase of arsphenamine reaction, can only be summarized from the limited knowledge available as in Fig. 168. The work of the late Dr. Burke (1931) of the Whitechapel Clinic is decisive evidence of sulpharsphenamine as the predominating factor in the production of this reaction since

1 Undoubtedly many unreported cases.
2. The actual frequency unknown and probably dependent on the drugs used. The proportion under "914 is probably low considering the enormous use of the drug under sulpharsphenamine high.
3. Mortality 50 per cent (Farley Burke, 1941)

APLASTIC ANEMIA CAUSES 5 PER CENT OF DEATHS

syphilis it appeared that the proportion of serious to total reactions caused by the two drugs was very similar 48 8 per cent for arsphenamine 606" and 45 4 per cent for neoarsphenamine (914)

GENERAL CONDITIONS AFFECTING REACTION

Age, Sex, Race.—The majority of reactions occur in the age groups in which intolerance of the drugs due t functional impairment of advancing years is t be expected. A partition of reaction incidence between youth and age was observed by the Cooperat ve Clinical Group (1933) which found that there as an increased incidence of mild reaction in the age groups fifteen t nineteen and twenty to twenty four consisting especially of gastro-intestinal and nitritoid reactions. As the age of the patient increased, mild reactions showed tendency t decrease, but severe reactions tended t increase in frequency This as especially true for crustaceous dermatitis (except in the fifteen to nineteen age group) and icterus, which rose from incidence of 0.5 per cent in the age group fifteen t nineteen t 1 6 per cent in the age group forty five to forty-nine Classifying reactivity by type of syphilitic involvement present confirmed these findings. Cole and his associates (1931) found that in older individuals treated with arsphenamine, more icterus was seen than among younger patients. Skin eruptive reactions were more frequent below thirty-five; pruritus above thirty-five. Nitritoid reactions were observed more frequently after this age. In contrast ith the earlier Cooperative Clinical Group findings, severe crustaceous dermatitis was observed almost entirely before the age of thirty-five. Hemorrhagic encephalitis as found by Cole and his associates t occur more frequently in young adulthood. The Cooperative Clinical Group found that mild arsenical reactions were twice as frequent in females as in males *in both colored and hit races; while severe reactions were seen more frequently in hites* without regard t sex. Cole and co-workers showed, furthermore, that whit omen are more reactive than Negro women. Waugh and Milovich (1940), reporting the experience of the Hot Springs treatment center of the United States Public Health Service found that there were 2.47 severe reactions per 1000 arsenical injections among the men, and 2.50 among the omen. The incidence was higher for whit men than colored men, but was higher for colored women than for white women. The single case of acute yellow trophy of the liver observed t Hot Springs occurred in a whit man, and the single case of agranulocytopenia with angina occurred in hite oman with secondary syphilis. These observers found 1 83 icterus reactions per 1000 arsenical injections among the men, and 1 14 among the omen, and no difference in the incidence of icterus as bet een whit and colored patients. Crustaceous exfoliative dermatitis was more the twice as common among omen as among men, and about the same for the hit and colored races. They found, furthermore that this reaction was almost t ice as common among hite

Tryparsamide	71 100	3	1	0	4	17 775	0
Total.	1,794,383	713	339	54	1 118	1,605	33 169

A cerebral hemorrhage following the administration of mapharsen.

women as among whit men, and four times more common among colored women than colored men. While the United States Naval statistics (1933–1941) cannot be used for comparative purposes here, the generally accepted idea that women are more reactive than men may to some extent account for the low incidence of reaction in the N val statistics which concern men, and young men at that. The rôle of pregnancy and other factors explaining the apparently increased incidence of treatment reactions to the arsenical in women will be presently discussed.

Rajam (1935) reported his experience with reactions and complications in the course of administration of 24,530 doses of neoarsphenamine to 7180 East Indians with syphilis. His statement that this race does not tolerate neoarsphenamine is well borne out by his figures; dermatitis was produced in 1 of each 120 patients treated, an incidence of 1 to 147 for men and 1 t 83 for women. The individual dose of neoarsphenamine never exceeded 0.3 Gm., yet there was 1 case of dermatitis for each 431 injections; 1 to 514 for the men and 1 to 204 for the women. There were 3 deaths. Jaundice, however was less than half as common, but in this series hemorrhagic encephalitis developed in 6 cases. In his masterly study of blood dyscrasias in the treatment of venereal diseases, the late E. T Burke (1941) found that approximately 0.5 per cent of women patients and 0.3 per cent of male patients in his Whitechapel series (1934–38) developed blood dyscrasias. Burke found sulfarsphenamine to be the common factor in all of his cases, but does not state whether more men or more women were treated with this drug

In connection with the effect of race, Sampson and Latven (1936) showed that there is definite and constant difference in the tolerance to neoarsphenamine of albino rats from different colonies or racial strains. It is apparent from their experiments that it is not possible to make a significant comparison of toxicity among samples of neoarsphenamine when rats from different strains are used.

Relation of Number of Treatments and of Dosage to the Frequency of Arsenical Complications.—There is little doubt that patients may acquire extraordinary tolerance t the arsenicals, as exemplified by the remarkable case of Photinos (1930) in which woman patient was given total of 191 Gm. of neoarsphenamine in 230 injections of which 190 were 0.9 Gm. each, during period of six years. This probably parallels the improvement in elimination shown by Underhill for the arsphenamines and Hanzlik for bismuth. As general rule, the percentage of persons having reaction rises from the sixth to the tenth injection, and then remains more or less stationary up t the sixteenth to twentieth injections. From this point there is further rise, which then declines t low point between the thirty-first and the thirty-fifth injection. Harrison (1930) and Cole and his coworkers (1931) have both observed severe reactions often from the seventh to the fifteenth dose. The Cooperative Clinical Group (1933) found that reactions either of the mild or severe type occurred with the greatest frequency during the first course of treatment, and dropped off gradually ith each succeeding course. Waugh and Milovich (1940) found that 87 per cent of the crustaceous dermatitis reactions occurred less than 2 months after the beginning of treatment. T enty-tw per cent followed 1 to 6 arsenical injections. In the Cooperative Clinical Group material 67 per cent of the crustaceous dermatitis manifested itself before the second month of treatment, 53 per cent following 1 t 6 injections, and 14 per cent following 7 to 12 injections. In Waugh and Milovich series, men received an verage of 11 injections of arsphenamine and the women 13. Burke (1941) believed from his experience that postarsphenamine bood dyscrasia is unrelated to dosage but that it tends to appear late in the course of treat ment. Our experience corresponds to that of Burke. It is probable that in this and some other types of reaction (g. hepatic) subthreshold injury begins long before the symptomatic reaction appears and can be detected by ppropriate tests (e. g blood smears and counts, icterus index).

Ireland, reviewing University of Pennsylvania experience, found that 75 per cent of reactions occurred before the tenth injection, 43 per cent between the first and fifth, and only 5.5 per cent after the twentieth injection. It is, of course, quite possible that the absolut validity of these statistics is impaired by the tendency of reacting patients to disappear from the records of clinics, but they at least represent everyday clinical expectation. Reactions involving high degree of individual idiosyncrasy vary enormously in their time of onset. Hemorrhagic encephalopathy tends t appear early and Cathcart and Stokes study of exfoliative dermatitis under conditions of hospital control found that most of the reactions occurred on small individual and total doses and in 6 cases out of 33 following the first injection of an arsenical.

Effect of the Type of Arsenical Drug on Reaction.—Sulzberger and Simon (1931) noted in connection with the differing qualities of various lots and brands of neoarsphenamine that there was varying sensitizing proclivity in man as well as in animals, for the various drugs. Cole and his associates (1931), in discussing the comparative number of complications among patients treated with arsphenamine and those treated with neoarsphenamine, found little or no difference in the number of reactions as between the two drugs (15 per cent reaction for arsphenamine and 16.7 per cent for neoarsphenamine)

Mapharsen (arsenoxide) it will be recalled, has as one of its strongest appeals and recommendations an exceptionally low incidence of reaction. Epstein (1941), compiling data from 92,000 mapharsen injections from his own experience and the literature found skin reactions, including exfoliative dermatitis, from one-half to one-third or even only one-sixth as frequent as with the other arsenicals. This was especially true of exfoliative dermatitis.

In common with Appel (1937), Jordon and Traenkle (1937), Cole and Palmer (1937), Astrachan and Wise (1938) Epstein (1941) therefore recommends the use of mapharsen in patients intolerant t other arsenicals He suggests, in view of the experience of Parsons (1937) Foerster and his associates (1935–37) Kalchar and Barnett (1936), and Marshall (1937) all of whom reported recurrences of crustaceous dermatitis after the intravenous injection of mapharsen or pruritus and erythema after such an event, that patch tests be used before the administration of mapharsen to previously dermatitic patients. Fatalities to mapharsen are extremely rare. Mention has already been made of the lessened toxicity of the mapharsen when used in the continuous intravenous drip method of massive arsenotherapy as compared with neoarsphenamine On the basis of lessened toxicity Rein and Wise (1939) have found mapharsen convenient medication for treatment of syphilis in office practice. In addition mapharsen has been advocated, contrary to our considered opinion unless under expert direction, as a substitution product for neoarsphenamine and other arsenical drugs in various of the severe reactions. A summary of the reactions to mapharsen is given in Fig. 108. Acetyl-glycarsenobenzene (sols-salvarsan) has been mentioned previously along with thio-arsene as drugs which have been abandoned in this country because of high incidence of reaction. Triodarsen s reaction incidence is relatively high for adults, though Glynn and Villa (1939) employing this drug in congenital syphilis, reported it well tolerated by intravenous and intramuscular routes. Bismarsen (bismuth arsphenamine sulfonate) has low incidence of reaction and in selected cases can be used as substitute for other arsenicals t which the patient is reactive. The incidence of hematopoietic accidents is low though few recent cases have been reported. Sulpharsphenamine, silver arsphenamine, neoarsphenamine and arsphenamine have been adequately discussed previously

Diet, Nutritional State Social Conditions, as Factors Influencing the Occurrence of Arsenical Reaction.—In the past decade much progress both clinically and experimentally has been made on the effect of diet and other nutritional states on the background of arsenical reaction. There have of course, been impressions that starvation, impaired nutritional states induced by the blockade in the First World War poverty and other factors predisposed patients t treatment reactions from the arsenicals. Müller insisted that bismuth tolerance in the German people was affected by starvation during the First World War Scholl (1942) ascribed w ve of arsenical dermatitis in 1940–41 to the avitaminosis that tends t prevail in the population during February March and April. Stümpke (1941) credited conditions produced by World War II with the observed increase in arsenical reactions in present-day Germany including the influence of the nutritional state, excessive fatigue, and nervous and mental conditions resulting from the War It is now clear however from studies beginning with that of Craven (1931) substantiated by Schifrin (1936) and recently further confirmed by Messinger and Hawkins (1940), that for the liver at least, diet plays major rôle in the prevention of damage by the arsphenamines. Craven showed that dogs on high fat and high nitrogen diet obtained maximum protection against liver injury resulting from the administration of arsphenamine. Of these two diets, Craven found that the former was more advantageous. A high carbohydrate diet, on the other hand, led to maximum susceptibility t liver injury caused by arsphenamine. He also indicated that starvation is an important factor predisposing toward liver injury caused by the arsphenamines. Cystine added to the diet or given intravenously did not increase the protective action of carbohydrate diet. Schifrin came to much the same conclusion as Craven, with reference to the failure of carbohydrate diets to protect the liver against injury from arsphenamine, even when large amount of glycogen was demonstrable in the liver He found, however in contrast to Craven, that high fat diet also left the liver sensitive t the ill-effects of arsphenamine but that diet rich in albumin was the most effective in preventing liver injury by this agent. Bearman (1934) using rats instead of dogs, could not confirm or disprove the contentions of either Schifrin or Craven. In 1940, Messinger and Hawkins found protein to be most effective in protecting dogs against arsphenamine liver injury On protein diet the liver injury was trivial and promptly repaired. They however found carbohydrat diet also beneficial but not as uniformly protective, and liver injury following this latter diet, hen it occurred, seemed more severe. Fat proved to be deleterious and the fat-fed arsphenamine-treated dogs showed markedly progressive jaundice, severe liver injury and intoxication to the point of death

Sulzberger working with Mayer Simon (1934) and others, on experiments with arsphenamine sensitization in guinea-pigs, found that guinea-pigs could be sensitized by intradermal injections of neoarsphenamine with great ease and regularity in Breslau, Germany Boston, Mass.;

Zurich, Switzerland; Odessa, Russia and Ottawa, Ontario. But with the same technique when fed on New York fodder it was practically impossible to sensitize New York guinea-pigs in New York City Sulzberger and Simon believed the cause of this variation in susceptibility t sensitization was not racial or constitutional, for New York guinea-pigs when transported to Breslau and Zurich could there be sensitized with ease Sulzberger and Mayer believed that green fodder (alkaline ash) inhibited and *dry fodder fa ored sensitization Further observations* reported by Sulzberger and Simon suggested that different lots of neoarsphenamine may have been factors in varying sensitizing effects as measured by so-called sensitization index in men as well as in animals. They believe that this index is independent of the actual toxicity of the arsenical as such.

In the past seven years beginning with the experimental work of Sulzberger and Oser (1934) there has been much interest in the question of relationship of vitamin C (cevitamic acid) t various types of sensitivity The problem has been studied by number of workers in connection ith rsenic sensitivity in animals and in man. Certain of these investigators found that vitamin C, administered by various routes, helped to prevent reaction to arsenicals while certain others have not been so convinced of the value of this vitamin as reaction inhibitor Durel (1937) fur thermore believed that using vitamin C in solvents for arsenicals reduced the therapeutic effectiveness of the drugs. This was denied by Dainow (1932 39) and partially by Cormia. This subject is in such stat of flux that it is impossible t the moment to say definitely whether vitamin C, administered orally or by parenteral route, has any significance in the reduction of arsphenamine reactivity On the other hand, there is accumulating vidence to suggest that such relation does exist, insofar as the use of vitamin C-containing solvents for neoarsphenamine administration has proven effective in reducing neoarsphenamine toxicity Furthermore, Cormia (1941) presented convincing vidence of the influence of vitamin C in arsphenamine sensitiveness, by giving 6 patients who had recovered from definite arsphenamine dermatitis, massive doses of vitamin C (500 mg. intravenously daily for seven days) After a cautious intravenous test with minute doses of the same brand of arsenical which had produced the cutaneous reaction, 5 of the 6 patients were eventually able to take full doses of the arsphenamine without further cutaneous reaction The patch test, previously positive, became negative in 3 of 4 patients subsequently tested. Cormia *kept his patients' vitamin C levels high by daily oral administration of 100 t 200 mg of the* vitamin. Abt and his associates (1940–1942) have attempted to desensitize patients t arsenicals by building up and maintaining their plasma ascorbic acid level at optional range. Their observa tions clearly indicate that vitamin C definitely counteracts the toxic action of neoarsphenamine and mapharsen in man. They showed that ascorbic acid prevents oxidation of arsenical solutions left in contact with air They further developed method which demonstrates that typical cutaneous reactions to neoarsphenamine in the majority of hypersensitive patients can be completely prevented by the addition of a sufficient amount of the ascorbic acid to the neoarsphenamine solution used for patch testing Recently Beerman, Pariser and Wammock (1945) successfully employed methylglucamine ascorbat solvent for reduction of mild arsenical reactions. Variations in vitamin A content of fodder do not pparently play role in intracutaneous sensitization of guinea-pigs to arsphenamine (Trei, 1940)

A tempting theory of the effect of vitamin C on arsenical reactions involves its apparent influence upon the allergic state, as suggested for example by Holmes and Alexander report (Science, November 27 1942) on the striking effect proportional to mass of dose of vitamin C on the arrest of hay fever This conception ould bear out Cormia apparent demonstration that sufficiently large doses of the vitamin given intravenously to maintain the blood level have marked anti-allergic effect, and hence in accordance with our previous discussion, could be ex pected to affect the incidence of arsphenamine sensitiveness and dermatitis, the former as ind cated by the patch-test discussed by Abt.

Wien (1938) also made study with large numbers of mice, to see the effects of simple varia tions in an ordinary laboratory diet on resistance of mice to mercurochrome and neoarsphena mine. His results confirmed the belief that in mice the toxicity of the drug is among other things dependent on diet. He was able t demonstrate for example that in toxicity determinations of neoarsphenamine preparations made on various diets, different values ere obtained for the ver age lethal dose under different diets He suggested that toxicity determinations for arsphenamine preparations be made simultaneously ith the standard brands.

There are additional reasons for believing that a high carbohydrate intake is unfavorable to the patient undergoing arsphenamine treatment. In the first place, its well-known tendency to exaggerate seborrheic processes increases the seborrheic predisposition toward exfoliative dermatitis. It contributes, moreover to pyogenic complications both in exfoliative dermatitis

and iodism. It promotes dental decay and to this extent negates the effect of mouth prophylaxis. There are, therefore, a number of reasons for believing that a high carbohydrate diet (incidentally particularly common among the poor) a low fat intake such as occurs in periods of blockade as in Germany during the War and fasting such as is a concomitant both of poverty and indisposition, may all work together to increase the tendency to arsenical reaction.

Seasonal Influences on Arsenical Reactivity—Reactivity especially serious, tends to occur in waves over periods of years and with a tendency to seasonal peaks The winter and early spring months seem to yield the higher incidence especially of liver and skin reactions.

Mention has already been made of Sulzberger's, Mayer and their associates work on the effect of differing geographic areas as factors in the sensitization proclivities of various arsenical drugs. This work, to some extent, is corroborated from the standpoint of the effect of seasons by the studies of Akiyama and his associates who found among the reactions occurring in 2016 cases treated with arsphenamine in the period from 1921 to 1937 that the arsphenamine exanthemata were seen most frequently in January and June.

The Cooperative Clinical Group (1935) made observations of the effect of different years in which the treatment was given on the incidence of treatment reactions to the arsenicals. The rate per 1000 injections for severe reactions dropped in all the clinics progressively from 1920 to 1931 inclusive. On the other hand, with mild reaction, after a great increase in the year 1921 the rate ran about level until the period 1926–30 when there was a pronounced increase which later dropped to the lowest level of the entire period. This increase in this five-year period seemed to be explained as due to greater care in observing and recording mild reactions. Perhaps because of increased attention to mild reactions, the rate of severe reaction fell to a level of only 1.6 per 1000 injections in the years 1929–31 as against 3.1 in the years 1920–22.

From 1925 to 1933, in a comparison of the yearly incidence of postarsphenamine and infectious jaundice Wile and Sams (1934) noted that nearly 60 per cent of their cases of late postarsphenamine jaundice occurred during the years 1930, 1931 and 1932. At the same time about half of the cases of infectious jaundice treated in the hospital from 1923 to 1933 occurred. Stokes, Ruedemann and Lemon (1920) and Ruge (1932) had previously noted a close parallelism between the occurrence of postarsphenamine jaundice and infectious jaundice. In connection with seasons, the incidence of intercurrent infection at various times of the year probably plays a part in the frequency of reactions and in their severity when they occur

Wile and Sams in their study of jaundice in syphilis found that there was a tendency for late jaundice to be slightly more common in the winter months, but this is not so marked as with infectious jaundice. This tendency has been previously noted by others (Todd (1921) Stokes, Ruedemann and Lemon, Ruge) Stokes, Ruedemann and Lemon definitely showed that their cases of jaundice were greatest in number during the months of respiratory and systemic infections, and approximately half the number had associated upper respiratory tract disturbances in the prodromal stage

Nedzel (1946) showed that in winter rabbits succumb to the toxic effects of neoarsphenamine more readily than in the autumn. A smaller number of rabbits survive without severe tissue damage in winter than in autumn. There is a larger number of severely damaged liver and kidneys among the surviving rabbits in winter than in autumn. In winter the livers of rabbits are observed to be relatively more severely damaged than in autumn. For kidneys the reverse relationship holds true. In white rats there were observed a relatively smaller number of severely damaged livers and kidneys in a May and June group as compared with a September and October group. Petersen (1942) has collected evidence indicating the close integration that exists between the meteorologic environment in which the human lives and the condition of the individual as it is reflected in changing susceptibility to drug intoxication.

Nervous States and Reaction to Arsenical Therapy—The influence of nervous factors on any of the arsphenamine reactions is difficult to evaluate Suggestion, apprehension, and undue emphasis on the likelihood of reaction on the part of the treatment room technician or physician at times seem to increase the occurrence of the immediate reaction. Milbradt, Gougerot and

others, including Spiethoff Becker and we ourselves, believe the vagus-sympathetic balance and vascular stability are affected both by arsenicals and emotional tension They are poorly tolerated by vagotonics, patients with toxic goitres and hyperthyroidism and in status lymphaticus.

The mechanism for the production of such effects at least for cutaneous reaction has been discussed by us (1939–40) In addition, the repetition of visits to the clinic or office with the concomitant repetition of the same emotions which the patient experienced at the time of the first visit, when the diagnosis of syphilis was made, may lead to a heightened emotional state on the part of the patient. Eventually prolonged therapy may lead to what Stokes has (1926) called the over treatment syndrome, in which the patient complains of a striking degree of nervous irritability Occasionally according to Cormia patients with this syndrome produced during arsphenamine treatment developed actual arsenical reactions, such as herpes zoster nitritoid crises, and thrombocytopenic purpura.

The following description is quoted from the first edition of this work

Arsphenamine Overtreatment Syndrome.—"There is, however an arsphenamine over treatment syndrome, quite as definite as that observed under mercury though much rarer Instead of becoming depressed, the patient becomes irritable, unstable, and emotional, at times almost hysterical The resultant hyperactivity and the anorexia and gastric disturbance due to nervous tension and hurried eating may lead to loss in weight. A typical case is easily recognized. The patient starts at the least movement or sound; the lips tremble and the eyes become suffused with tears at the slightest sharpness of tone in the examiner In neurosyphilitic patients marked exaggeration of such symptoms as ataxia occurs, not because of cord changes, but because of increased self-consciousness and nervous anxiety A patient once graphically described the mental state to me: "You know how it feels to hold an apple in both hands and twist it so as to break it in half?" he said. "There comes a moment when you can feel as you put the strain on it that the apple is just about to "pop and crack part. Well, I feel like that apple. Bromides, suspension of arsphenamine treatment, and a fishing trip or vacation usually produce a prompt recovery The condition does not appear in patients who have had arsphenamine a year or so before, so that it should not be used as an excuse for under-investigating syphilophobia or patient who comes with the background of latent or asymptomatic neurosyphilis.

Pregnancy and Toxemia of Pregnancy in Treatment Reaction.—The normal effect of pregnancy on the various organs of elimination would lead one to suspect that any other extraneous influence with potential hepatotoxic and nephrotoxic action would increase greatly the likelihood of reaction to the arsenicals in pregnant women. Furthermore the question of whether arsenicals given to pregnant women could possibly increase the likelihood of the so-called toxemia of pregnancy needs fuller investigation.

Several recent discussions of the subject, particularly that of the Cooperative Clinical Group (1936), by McCord (1935) and by Cole (1937) convey the impression that pregnant syphilitic women tolerate arsenical therapy well. McCord has apparently never seen serious treatment reaction or death in the medical supervision of more than 2000 syphilitic pregnant women. On the other hand, Ingraham (1939) in carefully documented study of the complications due to arsenical therapy in syphilitic pregnant women, recorded 7 maternal deaths, the study being based largely on data obtained from antisyphilitic therapy reported from six different sources to the Committee on Maternal Welfare of the Philadelphia County Medical Society since 1931 He was able in addition to collect 35 more deaths from the literature which he believes indicate that the pregnant syphilitic woman is not exempt from any of the severer types of treatment reaction, such as hemorrhagic encephalitis, acute circulatory collapse, damage to liver arsphenamine dermatitis and aplastic anemia, all of which have been causes of death. He believes, moreover that there is evidence to indicate that antisyphilitic treatment may aggravate an already existing toxemia of pregnancy or precipitate an incipient one Moore (1939) has taken exception to Ingraham findings and in study sponsored by Moore and made by Peckham (1911), it was shown that in a series of 13,742 consecutive deliveries at the Johns Hopkins Hospital, the incidence of toxemia of pregnancy was somewhat lower in syphilitic than in non-syphilitic patients. N cor-

relation could be established in the study between the stage of syphilis at the time of its diagnosis and treatment during pregnancy and the frequency of toxemia. Peckham concludes that antisyphilitic treatment administered to syphilitic women during pregnancy does not increase the incidence of toxemia of pregnancy. The question of the influence of pregnancy on treatment reaction is still open, but we feel that conservative individualized therapy during pregnancy with careful attention to detail will yield little or no excess of untoward reaction, in spite of the fact that individual isolated cases of serious reaction may occur in spite of careful control.

In explaining reactivity in pregnancy there seems reason to invoke the influence of nutrition, hygiene, age, nervous state of the patient, and similar collateral factors, too easily overlooked.

Two other considerations involved in pregnancy deserve special mention. Bismuth has been charged with an abortifacient effect of which we have seen no evidence; tryparsamide should not be employed in the pregnant woman because nothing is known of its possible effect on the optic nerves of the child, irrespective of the mother; and malarial therapy should not be invoked during pregnancy, both because of its own serious effect and the abortifacient action of quinine.

Intercurrent Infection and Disease.—One of the enemies of the patient under treatment for syphilis is intercurrent infection, acute, focal, or chronic systemic in type. The large majority of patients carry an unsuspected total load of accessible foci which is added to from time to time by common colds, tonsillitis, infectious diarrheas, grippe, influenza, and bronchitis.

While this subject has been best worked out in connection with cutaneous reaction, undoubtedly the principles can be extended to apply to other types of reaction occurring in patients receiving arsenicals who are subject to intercurrent disease, fungus infection, or foci of infection. The role of intercurrent infection in untoward reactions to antisyphilitic treatment can be divided according to Dudley Smith (1936) into two parts: 1, the harmful effect of antisyphilitic drugs on other infections; and, 2, the part which intercurrent infections play in producing harmful reactions in syphilitic persons. In 1931 Moore and Keidel published an extensive study relative to the appearance of various skin diseases, including exfoliative dermatitis and other less complex reactions such as urticaria, erythema, herpes simplex and so forth following antisyphilitic treatment with arsenicals. They intimated that the secondary dermatoses like herpes could possibly result from something more than the actual local toxic effects of the arsenic, and were inclined to accept Milian's contention (1935) that certain eruptions produced by the arsenicals are like acute exanthemata such as measles, and due to a lighting up of latent bacterial infection. Stokes and Cathcart (1925) were pioneers in calling attention to the influence of focal and intercurrent infections on arsenical dermatitis. In 1934 Stokes and Kulchar extended the concept to include dermatophytosis. According to these authors a part of the influence of infection was probably exerted through the allergic mechanism of arsphenamine sensitization, and involved the conception of multiple balanced and summation effects as suggested by Vaughan (1937) in general, by Harkavy and Hebald (1938) for infectious asthma and arthritis, and by the observations of Moore, Woo and Robinson (1931) on the reactivity of atopics to arsphenamine intradermally. When the infection involves the skin in antecedent or induced dermatitis from other causes, the local dermatitic focus acts as an excitant to the general flare-up following arsenical medication. Dermatophytic infection may apparently act as a participant in a balanced or "summation" allergic complex involving an arsenical, an arsenical extending the range and increasing the severity of the allergic dermatitis response to the drug. A dermatophytic focus may also conceivably serve through the induction of local vasodilatation as the starting point of an "arsenical" dermatitis. Minute amounts of arsphenamine in arsphenamine-sensitive patients may flare up and generalize a local, apparently mycotic, dermatitis. The interaction of a drug on infection allergy may be reversible, and may in some cases take the course of Milian's "activation" of the infectious focus with the appearance of an exanthem of the toxic erythema type and a flare-up of the local focus in the case of bacterial infection, or an exacerbation of a localized mycotic process or a "mycotid" in the case of a fungus infection. Their experience led Stokes and Kulchar to suggest that in dealing with an arsphenamine dermatitis in patients with focal infective lesions, mycotic or bacterial, treatment should be directed, albeit with caution, at the focal as well as at the general process.

In 1937 Stokes and Callaway expressed the opinion that intercurrent infections like influenza may exercise a sensitizing influence to pyogenic and mycotic dermatoses as well as to light. Smith, in his study quotes number of observers, one of whom, Weiss, pointed out in 1925 that fatal accidents following antisyphilitic treatment sometimes can be prevented if caution is observed in treating patients with acute infections, especially pneumonia. The pneumonia induction may be in part due t mechanical and allergic effects involving the pulmonary circulation. He also cited Cormia (1936) in his work on experimental arsphenamine dermatitis which showed that staphylococcus toxin did not increase the incidence or severity of the reactions to arsphenamine in guinea-pigs, and similar results were observed in guinea-pigs infected with streptococci. Smith comment that this does not reproduce the situation found in intercurrent infections in man. Later (1938) Cormia found in contrast with his earlier result that in the presence of low vitamin C diet, chronic focal infection with group C hemolytic streptococcus definitely accentuated the manifestations of cutaneous arsphenamine hypersensitivity This effect was inhibited by high vitamin C int ke hich either reduced arsphenamine reactiveness or increased resistance to the

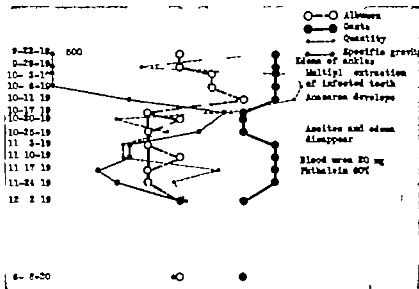

Fig 173.—An illustration of the increased load throw on the kidney by focal infection The patient entered with marked nephrosis, thought t be due to amyloid degeneration. When the focal infection in the teeth was stirred up in the process of extraction he grew markedly orse, albumin increased, and edema and anasarca appeared As he recovered from the xtractions, these signs disappeared and gradual improvement of the renal condition took place, with complete recovery in tw years. His tolerance of treatment as greatly improved and the ultimate therapeutic result as excellent (syphilis of the liver)

streptococcus infection Netter and Urbain (1931) felt, from their studies with the virus of herpes zoster that arsphenamine as well as other agents is responsible for cases of secondary zoster because the drug possibly stirs up to activity latent virus in the ganglia. Much of the jaundice which occurs during arsenical therapy and is attributed t the toxic effects of the drug is in all probability the expression of an epidemic of infectious hepatitis. (Stokes, Ruedemann and Lemon Ruge Wile and Sams; Lane (1939) and others)

The effect of chronic focal infection (dental) in reducing tolerance of treatment is well shown in Fig. 173 in which disturbing a focus of infection decreased treatment tolerance to be followed by improvement on complete removal. The attacks of cystitis and pyelitis associated with infected tabetic bladders are a serious menace though the tolerance of some of these patients for treatment in the intervals between attacks is remarkable and tends to bear out McFarland observation that the kidney while one of the most

abused is probably one of the most tolerant of organs. Fever is a definite contraindication to the administration of the arsphenamines, regardless of cause and particularly so if tuberculosis, respiratory or a chronic pyogenic infection underlies the temperature. Glycosuric diabetics, patients with hyperthyroidism and toxic goiter known cases of lymphatic struma and hemophilia, are very reactive to arsphenamine therapy particularly

Alcohol and Reaction.—The one drug which observation convinces us is dangerous to the patient under treatment for syphilis is alcohol. Its action in favoring cutaneous disturbances such as seborrheic eczema and psoriasis, its stimulating effect on pyogenic infections (furuncle and carbuncle are the terror of the alcoholic as of the diabetic) its vasodilator effect in flushing the skin and promoting vascular instability its possible effects on the liver and its tendency when freely used, to produce a pathologic picture in delirium tremens essentially similar to that produced in hemorrhagic encephalopathy all seem to us unmistakable warnings as to its possible pathogenic rôle in treatment reactions. Its unfavorable effect upon syphilis as a disease is elsewhere discussed.

Disability Due to Syphilis as a Cause of Reaction.—Under this title must be included chiefly the considerations relating to therapeutic shock (Herxheimer effect) and therapeutic paradox discussed on pages 131 and 132 and in connection with syphilis of individual groups of structures in subsequent chapters Where syphilis paves the way through degenerative change for invasion by infection as in the case of the tabetic bladder and the atonic intestinal tract or the duodenal ulcer in the tabetic, it may be conceived as a contributor There is, however no evidence that the syphilitic by virtue of his syphilis *ipso facto* is either more or less tolerant of antisyphilitic drugs than is the normal person.

The Cooperative Clinical Group (1933) found that in early syphilis, the rate for mild reactions was three times higher than for severe reactions. Severe reactions, however showed their highest incidence in primary syphilis followed by lessened incidence in secondary and latent syphilis. Waugh and Milovich (1940) report showed the incidence of severe reactions to be about the same in all the earlier stages of syphilis; being 2.4 per 1000 arsenical injections for primary syphilis, 2.60 for secondary syphilis and 2.41 for latent syphilis. They also found that the incidence was considerably higher for the white patient with primary syphilis and slightly higher for white patients with secondary syphilis. In latent syphilis the incidence for the colored was slightly higher than that for the white patient. Cole and his associates, in their attempt to determine whether the stage of syphilis during which the patient began treatment influenced the type of complication occurring, found that among the early cases the incidence of gastro-intestinal reactions was 27.3 per cent whereas among the latent cases the percentage was nearly doubled—50.6 per cent. A much higher percentage of patients with early syphilis suffered slight skin reactions than of those who began treatment while in the latent stages. There were twice as many nitritoid reactions among the latent cases as among the early cases. Patients with treatment resistant syphilis have been found to be specially reactive to the arsenicals by Jessner (1923–1929) and by Beerman (1936) This fact may be indirectly concerned in the production of treatment resistance since reacting patient can only be given smaller doses which in turn may produce treatment-resistance

One does, however gather the impression, probably more or less traditional that antisyphilitic treatment is better borne by syphilitics than others. In our experience the paretic patient, particularly of the degenerated type, is astonishingly tolerant of huge dosage and protracted treatment which would be borne with difficulty if at all by patients of other types or by normal persons.

System of Treatment as Affecting Reaction.—The Cooperative Clinical Group's investigations in early syphilis have apparently shown that there are significant reaction differences in the aggregate between patients under continuous intermittent, intensive and irregular regimens.

Continuous treatment causes more minor but no more than, if as many major reactions as the definitely less effective intermittent treatment. Jaundice is half as frequent again under intermittent as under continuous treatment, the severe gastro-intestinal disturbances are only slightly more frequent in continuously treated patients; exfoliative dermatitis is approximately as frequent under the one system as under the other; kidney damage is three times as frequent under intermittent as under continuous treatment; and aplastic anemia and purpura about four times as frequent under intermittent as under continuous treatment.

If these figures sustain confirmation in more extended studies they certainly argue that the patient should not be denied the advantages of continuous treatment from the curative standpoint on the theory that he is seriously endangered by grave complications. The minor reactions, including nitritoid crisis, seem to be the only real handicap to the superior continuous system of treatment. The influence of the simultaneous use of a heavy metal with the arsphenamine has already been referred to. It appeared from this study that in any regimen in early syphilis where much heavy metal was given, with or without much arsphenamine, the reactivity was high. It was not greatly increased even by vigorous arsenical treatment (53 *versus* 56 per cent). The minimum of serious reaction is obtained by much arsphenamine and little or no heavy metal, and by much arsphenamine alone. These facts are in accord with the previously mentioned observations on the tendency of reactions to diminish in the longer courses of treatment rather than to increase on the rise of renal tolerance observed by McFarland on stepping-up of elimination discussed *in the previous chapters. They all tend to indicate that the body* acquires a definite tolerance of treatment for syphilis which is an asset in an unknown proportion of cases.

THE GENERAL CLASSIFICATION OF REACTIONS

A certain amount of confusion inevitable on an attempt to retain in memory the enormous range of reaction to treatment for syphilis can be prevented by an attempt at classification. This serves the additional purpose of providing a background for certain general treatment principles which the therapist can have at his finger ends both in knowledge and equipment for dealing with the large majority of cases. Such a schematization is outlined in *Fig 174 and should be carefully inspected. Group I includes therapeutic shock* and therapeutic paradox, fully considered on pages 131 and 132, together with their prevention by means of preparatory treatment (p 220). The effect of structural impairment has been largely considered under general causes of reaction. Group II includes first the general conditions affecting the patient, as previously discussed secondly idiosyncrasy and pseudo-idiosyncrasy and acquired hypersusceptibility *including allergic effects and precocious ter* tiarism.

Idiosyncrasy and Pseudo-Idiosyncrasy as Factors in Reaction.—Idiosyncrasy to antisyphilitic medicaments is an undoubted fact and established beyond question. The statistical and individual study of reaction would tend to indicate that it is particularly important in hemorrhagic disease in some

cases of exfoliative dermatitis occurring on first exhibition of a drug, including arsphenamine, bismuth, mercury and the external application or oral administration of iodide. Individual instances of idiosyncrasy are discussed under the various drugs on pages 213 217 220 257 The aggregate importance of the idiosyncrasy factor cannot be estimated in per cent, but the observer cannot avoid being impressed with the fact that this category of complications seems abnormally frequent among those whose experience with the treatment of syphilis by modern methods is comparatively small. One is led to suspect, therefore, that inexperienced therapeutic management is at least an important factor in the production of what might be called pseudo-idiosyncrasy The patient who is idiosyncratic to all the drugs used in the treatment of syphilis

Fig 174.

A CLINICAL CLASSIFICATION OF REACTIONS

For the Discussion of Prevention and Treatment

1. Reactions contingent on the disease.
    ( ) Therapeutic shock (Herxheimer effect)
    (b) Therapeutic paradox.
    (c) Structural impairment.
2. Reactions contingent on the patient.
    ( ) General conditions.
    (b) Idiosyncrasy and pseudo-idiosyncrasy
    (c) Hypersusceptibility (including allergic effect and precocious tertiarism)
3. Blunders.
    ( ) Acid arsphenamine.
    (b) Toxification of drugs.
    ( ) Water errors
    (d) Tubing reaction.
    (e) Embolism.
    (f) Infection.
4. Technical error
    ( ) Intramuscular injection.
    (b) Intra enous injection.
    ( ) Spinal test.
5. Drug reactions as such.
    ( ) Mouth.
    (b) Gastro-intestinal
    (c) Vascular
    (d) Hematopoietic.
    ( ) Cutaneous.
    (f) Hepatic.
    (g) Renal.
    (h) Pulmonary
    (i) Nervous system.
    (j) Special sense organs.

at one and the same time deserves a very full and careful general medical and at times even a neurological or neuro-psychiatrical examination as well as a dermatological and allergic study to determine the underlying factors and the possibility of their elimination. Among the most common causes of pseudo-idiosyncratic reactivity on the part of patients should be mentioned the following

Causes of Pseudo-idiosyncrasy.—1 Nervous reactivity produced by fear of the disease, noncomprehension of the instructions for the prevention of reaction, underlying neurosis and hysteria, and psychic and physical trauma and pain inflicted in the course of bungling and sometimes even expert treatment.

2 The cutaneous sensitizing effect of technically incorrect intravenous injection of the arsphenamines which allows part of the first dose of the drug to infiltrate the skin. This topic, discussed on page 254 is in reality an aspect of acquired hypersusceptibility

3 Hyperreactivity simulating idiosyncrasy and sensitivity but due in reality to technical errors, first and foremost of which is too rapid or too slow injection of intravenous medicaments. It is impossible to lay too great stress on this factor in the production of pseudo-idiosyncrasy

4 Hyperreactivity simulating idiosyncrasy but due to disregard of an analyzable tolerance factor which is considered in the next section under general principles of reaction prevention.

Where, in spite of attention to all the details involved in the above items, the patient is still persistently reactive, the practitioner would be well advised to secure expert advice before abandoning treatment or increasing his difficulties by haphazard trials of various possibilities. Shift of drug and various substitutions are considered on page 389

Hypersusceptibility and Allergic Effects in Reactions.—These are presented in detail on page 253

Induction of Precocious Tertiarism by Inadequate Treatment.—Precocious tertiarism and violent allergic response to a syphilitic infection following a few injections of a trivalent arsenical is a phenomenon of an entirely different order from trivalent arsenical cutaneous sensitivity and probably involves the reaction of the tissues to the disease-producing agent rather than to the drug used in treatment. The frequency of induced malignant syphilis or precocious tertiarism as the result of two or three injections of a trivalent arsenical followed by a rest period or lapse, is not precisely known but the dangerous and destructive reactivity thus induced by inadequate treatment is a serious complication In the chapter on relapse illustrations of the huge ulcerative lesions, the intractable gummatous manifestations, rupial eruptions and so forth, which may follow the suspension of treatment in a patient who has received only a small amount of trivalent arsenical without heavy metal protection, are well illustrated (Figs 423 434) The remedy is an obvious one —under no circumstances should a patient particularly with early syphilis be given an arsenical without an accompanying or ensuing heavy metal and inasmuch as most instances of precocious tertiarism occur in patients who have lapsed treatment before it was thought advisable to introduce the heavy metal therapy this fact seems a justifiable argument in favor of simultaneous use of the two types of drug rather than their alternate use. Malignant syphilis and precocious tertiarism should largely disappear when the axiom "No short courses and no arsenical without heavy metal" is universally accepted.

THE GENERAL PRINCIPLES OF REACTION PREVENTION

The foregoing section has dealt largely with the inevitable. The ensuing section will deal with those forms of reaction which result from blunders, technical errors and drug reactions as such, and which are therefore largely avoidable and to a high degree treatable. Before considering them individually the general principles of reaction prevention and treatment may be reviewed

General Appraisal and Restorative Measures.—As in the determination of the aims and possibilities of treatment, so in the prevention of complications the first essential to a reactionless course is a thoroughgoing physical ex

amination with a consideration of the general factors influencing tolerance and reactivity as discussed in the preceding section.

With distressing frequency the single-track mindedness, so to speak, which one of us (J. H. S.) has labeled with the term "Wassermannism" or "serologism" (see Fig. 150) leads to the initiation of treatment without even a preliminary effort to survey the situation with reference to tolerance. The sight of a positive serologic report is to the uncritical doctor like the sighting of the "Jolly Roger" in piratical days, a signal for opening fire without parley irrespective of whether the opponent is yawl, sloop or frigate. If the patient be sound in wind and limb, he will probably tolerate all that may be needed to control or cure his infection. If on the other hand, he present remediable defects, they should be identified and corrected.

It is desirable at the outset if possible to initiate a physical overhauling which restores the infected person to the general level of normality for his time of life. The removal or treatment of focal infections, early rather than late, general hygiene, mouth prophylaxis, attention to diet, alcohol, and constipation, each becomes individually important. The essentials of this mouth prophylaxis are given in Fig. 175, the measures aiming in general at

Fig. 175.

ORAL HYGIENE FOR THE SYPHILITIC PATIENT

1. Carious teeth out or filled.
2. Gum pockets cleaned and treated, teeth scaled.
3. An alkaline potassium chlorate toothpaste used twice daily with a medium brush.
4. Wash mouth after eating with zinc chloride mouth wash (½ of 1 per cent in Liq. antisepticus alkalinus).
5. Clean dentures as well as teeth.
6. Then paint gums inside and out with a mixture of 1 part tincture kino, 2 parts tincture of myrrh.
7. If signs of salivation or gingivitis appear, change to half strength hydrogen peroxide solution.
8. Have buried teeth out at the start.
9. Have gum flaps over third molar teeth removed.
10. Watch devitalized teeth closely. If possible remove them, substituting adequate removable and cleanable dentures.
11. Avoid devitalizing teeth during treatment.
12. With mercurials avoid acid or sour foods.
13. For the best mouth hygiene, avoid sugar and sweets.
14. Remember bismuth pigment betrays the patient to family or dentist.
15. Dental help is desirable but much can be done *without it*.
16. Dental hygiene should precede tonsillectomy.

the discouragement of saprophytic flora and the prevention of the formation of hydrogen sulphide in the mouth.

Dietary Management.—This should be appropriate to the situation, and is summarized in Figures 178 and 179.

Instructions to the patient for the management of the gastro-intestinal phase of his reactions in so far as he can take care of it himself are given in Fig. 176.

Preparation and After-care—Vigilance.—The cardinal ingredient of all plans to prevent reaction is unremitting alertness and vigilance. It is impossible to overemphasize this element in the prevention of trouble for it constantly suffers obscurity and lapse even in the best regulated practices and clinics. The initial energy required to bring the safety factor in treatment

to the highest possible level is very high and a service directed by an apathetic, overworked or fatigued chief and personnel may be counted upon to yield a considerable crop of reactions, unfortunately many of them serious. Even in a relatively leisurely office practice it is difficult and even annoying for physician and patient to go time after time through the seeming rigmarole which

Fig 170

A GASTRO-INTESTINAL REGIMEN FOR THE PATIENT UNDER TREATMENT

1 Encourage regularity in eating, slow chewing
2 Relieve anxiety for its depressant effect on the tract in some, its induction of spasm in others.
3 Meet constipation by considering the type, put high-strung nervous patients with spasm on bland diet, atonic types on roughage and increased fluids with exercise and massage
4 The tendency of treatment is to produce diarrhea not constipation. Therefore avoid roughage in general.
5 Avoid catharsis, except mildly after arsphenamine.
6 Do not give cascara as a cathartic. Use mild saline, castor oil, or phenolphthalein.
7 A mild laxative is better than an uncontrolled constipation under treatment, but a curative regime is even better
8. If enemas are used, employ physiologic saline, or water
9 Permit meat, eggs, fish, the softer vegetables (avoid fruits with small seeds, use tomato pulp and juice, excluding seeds) baked potato three times weekly graham bread, cooked whole-grain cereals. Limit desserts to custards, junkets, gelatin, with little sugar pulpy and seedless fruits, unsweetened. The coarser vegetables (spinach, celery radishes, onions, turnips, cabbage) must be cooked and put through a strainer or very finely comminuted
10 Emphasize fats by insisting on ( ) whole milk reinforced by cream, ½ to 1 pint to the quart (b) butter and salt or cream on cereals (no sugar); ( ) butter on vegetables; (d) cream, whipped, on desserts; ( ) mayonnaise and oil dressings; (f) peanut butter (g) nuts (h) cream with effervescent mineral waters in underweight patients (8 oz., equal parts, between meals) Avoid during intensive arsenical therapy
11 Sharply restrict or exclude ( ) sugar as candy honey syrups, soda-fountain and effervescent or syrupy drinks, ice-cream, pastries (b) the starchy puddings (rice, cornstarch bread pudding, dumplings); ( ) high proportions of macaroni rice corn meal (d) bran as such.
12. The Vitamin groups A and B may be increased by cod liver and halibut liver oil and by wheat germ or brewers' yeast respectively and the B group should be added to high fat diets (ketogenic type) Vitamin C may be given in tablet form or as solvent for the arsenical
13. Edentulous patients must have dentures or use the meat grinder
14. Administer alkalis only for definite reason, avoiding the soda and magnesia habits.
15 Do not give hydrochloric acid by mouth to patient on heavy metal (risk of salivation) without special precaution (alkaline rinses, etc)
16. Avoid sour foods in mercurial therapy (see Oral Hygiene)
17 No more than light wine for carminative effect with meals, and not that except for medical reasons. No *cocktails, highballs, "hard" liquors.*

if conscientiously carried out, is the essential ritual of protection In the effort to systematize these elements in our own practice and clinic we have tried to emphasize four items

(1) The proper questioning of the patient as to his response to the previous treatment (2) a minimal medical inspection (3) weekly observation with the occasional performance of indicated special tests, including urine differential blood count and icterus index and (4) systematic instruction of the patient in a technic of preparation and after-care Particularly when treatment is to

be conducted as an ambulatory procedure, the conscientious carrying out of detail under these four heads will be found a great aid in the general prevention of reaction.

The Questionnaire.—In 1931 one of us (J H S.) drew up a question form mounted on a card under celluloid which was presented to each literate and reasonably intelligent patient to be read and answered by him before each treatment. This question form is shown in Fig 177 A card or chart bearing it may

Fig 177

PREPARATION OF PATIENT FOR TREATMENT—QUESTION FORM

Questions To Be Answered Before Receiving Treatment:

Each time the nurse prepares you for treatment, she will hand you this card. Please read the questions one at a time out loud and answer each one in her presence. Think carefully and give correct answers. In this way you can do a great deal to protect you from disturbance or reaction caused by the medicines you are receiving.

1. *How do you feel?*
2. Were you sick at your stomach, or were your bowels loose after the last injection.
3. Any trouble with arm or hip?
4. Is your mouth sore?
5. Any pain down the legs?
6. Did you itch?
7. Did your skin get red or break out?
8. Is it red, itchy or broken out anywhere now?
9. Are you getting up nights to pass water?
10. Is your urine dark or reddish in color?
11. Did you bleed from the gums?
12. Were your bowel movements black
13. Were your bowel movements white or clay-colored?
14. Were or are there any spots on your skin since last treatment, especially black and blue ones?
15. Are you having a cold? Is it in your head or chest?
16. Is the trouble for which you came to us getting better or worse, or is there no change?

be mounted or painted on the waiting room or treatment wall. Where the patient cannot be relied upon to read it intelligently the questions should be asked, if necessary with the aid of an interpreter or by sign language to secure the required information. The responses to these questions cover practically all of the warning signs of a developing intolerance of over-dosage and too-rapid injection of incorrect intramuscular intravenous entry and injection of impending jaundice, dermatitis and purpura of the onset of an acute respiratory infection and of the progress of the patient. It is impossible to overemphasize the extreme importance of the questions relating to itching rashes, and signs of hemorrhage. Time and again patients admitted to wards of hospitals in serious condition and conscientious physicians attending them have given unmistakable accounts of symptoms which were either not fully inquired into or slurred over at the injection next preceding the one which resulted in a perhaps fatal exfoliative dermatitis or hemorrhagic complication. In our own experience and observation this has happened *a number of times even in* services and practice which we supposed we had under complete control. Such experiences illustrate less the inevitability of grave consequences from a lapse in vigilance than they do the paramount necessity for maintaining standards of practice fully comparable to those of the best surgical and other critical forms of medical work.

Emphasis should here be placed again upon the significance of nitritoid

reactions (see p. 244) and gastro-intestinal intolerance as warnings of a developing inability to carry treatment unless compensated by detoxifying measures. Not alone for the subjective relief and improved cooperation of the patient, but because it is positively dangerous to permit steadily increasing increments of reaction to grow unchecked, the appearance even of the minor types of reaction in a patient should be closely watched and scrutinized for every possible cause Vigilance does not, however protect against the idiosyncratic factors involved in hemorrhagic encephalopathy exfoliative dermatitis and fulminating acute arsenical poisoning with atrophy of the liver

Minimal Medical Inspection.—Many patients are not sufficiently observing nor do they present evidence visible to them, of impending complications. Accordingly a minimal medical inspection is indispensable to a smoothly conducted practice. The recommendation that a patient be stripped and completely examined before each treatment is ideal but impracticable. A reason

Fig 178.

PREPARATION OF PATIENT FOR TREATMENT—
MINIMAL MEDICAL INSPECTION

Fix your eyes on the patient face, the bared neck (and shoulder if possible) the bends of the elbow and the wrists and look in the mouth. Have him drop his sock or stocking.

Before treatment is given be sure you have inspected

1 **Condition of the Available Veins.**—Palpation is quite as important as inspection, for *thrombosed vein can sometimes be recognized as such only by the way it jumps* under the palpating finger and resist compression.

2. **Condition of the Buttock.**—Deep induration should be sought for together with any trace of erythema, superficial nodules, tenderness over the sciatic nerve, uncomplicated deep tenderness.

3 **Pink stippling or signs of irritability (rash) of the skin about the neck, the face the elbow flexures.** The latter especially will be seen on baring the arm for intravenous injection and may pass unnoticed by the patient.

4 **Color of the Sclerae.**—The patient should be viewed in good daylight, if possible

5 **Petechiæ** on the gums, ankles and wrists.

6. **Fetid odor of the breath.** This suggests bismuth overdosage.

7 **Involution or progression of visible lesions of the disease** especially chancre and secondaries.

MANY COMPLICATIONS GIVE DEFINITE WARNING LOOK FOR THEM
AN OVERSIGHT MAY BE FATAL

able compromise with this requirement is presented in Fig. 178 In highly organized clinics such as that of Colonel Harrison at St. Thomas s Hospital, London, the medical officer charged with the duty of passing the patient for treatment occupied a definite station with a strong daylight illumination or daylight corrected electric light playing upon the patient. The objection of private patients to divesting themselves of enough of their upper garments to expose neck, arms, and shoulders must be overruled Dermatitis most frequently appears at the flexures and on the face below the eyes and sides of the neck· purpura on the mucosae and about the wrists and ankles. The beginnings of the nitritoid reaction during treatment cannot be detected satisfactorily without this degree of exposure at the time the injection is given If the physician will retain the items on which he desires information in mind during the process of the treatment interview he will find it possible without embarrassment to cover each and every point. His principal problem will be to remember and

to take the time. Finally only by observing the state of the active lesion for which the patient is being treated can one judge of the efficacy of much of the treatment and the effectiveness of the drugs. It is particularly desirable to

Fig 179

DIRECTIONS TO THE PATIENT TO BE FOLLOWED BEFORE AND AFTER TREATMENT

Before the "Arm" Treatment:
1. Bowels should move the morning of the treatment day. Take mild laxative the night before if in doubt or ask for directions if habitually constipated.
2. Plan to eat very lightly the meal before treatment and the meal after: tea and toast, cereal, no meat, no rich foods, nor coarse vegetables.
3. Eat nothing within two hours before treatment.
4. Report cold, cough, sore throat, loose bowels, fever before you come for treatment.
5. Watch your skin, bowels, urine, and report anything wrong before treatment, whether questioned or not.

After the "Arm" Treatment
1. Go home and lie down if possible. If not, try to avoid physical work and moving about. If feeling out of sorts, go to bed.
2. Eat lightly the meal after treatment. Under no circumstances eat meat, coarse vegetables, sea food, or pastry.
3. On the following day resume full diet.
4. While taking treatment eat freely of meat, eggs, butter and cream. Avoid starches and sweets.
5. Use no alcohol.
6. Do not be unnecessarily alarmed over headache or stomach upset after treatment. Take chipped ice, chewing the ice and swallowing it without letting it melt in the mouth. If decidedly nauseated, swallow a glass of water containing level teaspoonful of baking soda, and vomit if necessary. Use ice-bag on the pit of the stomach if possible. Report by telephone if not relieved. For headache, use cold compress or ice-bag.
7. If more than four liquid bowel movements, follow treatment within six hours, accompanied by cramps, take teaspoonful of paregoric every half hour for 3 doses; eat only hot milk toast and stay in bed. Report if not relieved.
8. If the bowels have moved less than three times before the morning after treatment, take cathartic before breakfast; either one-half bottle of citrate of magnesia, or glass of Pluto water or tablespoonful of Epsom salts or an ounce of castor oil with orange and lemon juice and a pinch of baking soda. If your bowels do not then move by afternoon, telephone for advice.
9. If the skin itches or breaks out after treatment, or becomes yellow or spotted, or the gums bleed, or the urine gets brown or red, telephone for advice.
10. Bring in urine specimen, 6 ounces, one half collected on going to bed, the other half on rising in the morning. Mix the two and put your name and the date on the clean filled bottle.

After "Hip" Treatment
1. The first three or four treatments may cause discomfort, but the tissue soon becomes accustomed.
2. There is usually some stiffness for two to four hours, or the day after treatment.
3. Use the muscles by walking, golf or other exercise to promote absorption.
4. Massage the hip over the injection deeply and firmly with the flat of the hand, especially just after treatment.
5. At bedtime, on three to five nights a week, fill the bathtub 6 inches deep with hot water. Sit in it, leaning back enough to keep the buttocks covered, and resting the feet on the end or sides of the tub, gently massage each buttock under the water, keeping it hot, and remaining in the sitz bath twenty minutes. This is preferable to hot compresses or the hot-water bag or electric pad.
6. Report any serious discomfort before the next treatment.

watch the involution of primary and secondary lesions when neoarsphenamine is being employed, for without darkfield control this is almost the only available means of detecting ineffective lots and drug resistance.

Weekly Observation.—Losing sight of the patient in hurry and routine leads particularly to accidents, and the ritual of inspection should be repeated even in patients on relatively mild medication at intervals appropriate to the drug and state of the case. The temptation, particularly under uneventful bismuth therapy is to have the technician carry through procedures week after week without more than casual inquiry Patients themselves become lax in the matter of bringing urine specimens, and insistence, amounting almost to discipline, is sometimes necessary Patients on heavy-metal therapy need questioning in regard to their local reactions, their gastro-intestinal tracts and mouths and evidence of polyuria and renal irritation particularly These items are covered in the general questionnaire which can be abbreviated to this extent in dealing with patients not receiving the arsenicals.

Instruction of the Patient in Preparation and After-care.—In ambulatory treatment especially the patient often becomes a more important factor in the prevention of reactions than the physician himself. For this reason it is essential to make every effort to interest and inform him without rendering him introspective or frightened. The direction sheet given in Fig. 179 outlines the essential requirements in a form to give to patients for their own guidance In a large treatment service it may be necessary to have a medical officer on call to meet the inquiries of patients, but the more closely the patient can follow these directions, the less the likelihood that he will need to summon aid Individual points will require emphasis and reemphasis and the reactions incident to a service, particularly in the minor field, will rise with the obtuseness of its clientele of course, but even more with the failure of the physician to put energy attention to detail and persuasive power with patients into his work.

Functional Tests—the Weekly Urine.—This was an essential feature of treatment in mercurial days under the bismuth regimen, weekly examinations are unnecessary but once in two weeks is a minimum of precaution with present knowledge. The items to be considered include evidence of renal irritation seriatim in the form of polyuria (low specific gravity) albumin casts, usually hyaline or granular and red blood cells. Abelin or Dickinson tests may be performed on urines by special students of the questions involved but are not recommended as routine, even in large clinics (Lloyd and Lloyd) All urines should be tested for bile, though it can usually be detected in the sclerae almost as soon as it is obvious in the urine. While pus is not an accompaniment of arsenical or heavy metal nephrosis, as a rule, its presence is important especially in tabetic neurosyphilis as evidence of the state of the kidney and bladder damaged by retention and infection. The phenolsulphonphthalein test for renal function should be performed at the outset in tabetics for the estimation of renal tolerance and general condition, but is unnecessary in the protection of the kidney during routine treatment.

Blood urea nitrogen should be obtained on tabetic patients before treatment is instituted, but is unnecessary as a routine except in patients under malarial therapy in whom a rise in blood urea nitrogen while under treatment is a danger sign.

Liver functional tests except as a preliminary to intensive methods such as intravenous drip are of debatable utility We do not believe it is necessary to obtain the icterus index after each arsphenamine injection as has sometimes been advocated, but it would seem advisable if the service has the facilities available or the private patient can afford it to secure this test once in six or

eight weeks during the longer courses of arsphenamine treatment which are growing in popularity or at any time that stormy course or puzzling symptoms appear

The development of a test for detecting cutaneous susceptibility in time to have preventive value would be a decided advance At the present time no such tests exist, the patch and intracutaneous sensitization tests described on p 255 being of known value only in detecting cutaneous sensitiveness after rather than before the explosion. On the other hand, these tests reach a considerable degree of value when employed for the differentiation of the so-called "ninth-day erythema" from the onset of exfoliative dermatitis and in deciding the fitness of a patient seen in consultation after a ninth-day erythema has developed for the continuance of arsenical treatment. The technic is discussed on p. 285

Periodic differential counts of the white blood cells with emphasis particularly on the appearance of an abnormal proportion of eosinophils and of nucleated reds are probably advisable in patients showing significant intolerance of treatment or in those receiving long courses. The indications must be determined by the individual case. Moore and Foley emphasize the value of such differential counts in warning of the seriousness of itching and slight rashes and of stomatitis as threats of impending exfoliative dermatitis or aplastic anemia. Schwind (1945) found in fourteen patients receiving five-day intensive drip arsenotherapy that there were no significant changes in the bone marrow of the patients in the absence of specific idiosyncrasy evidenced to arsenical drugs.

Special Tests in Pregnancy—Before an intravenous injection is given to a pregnant woman and on each occasion a blood pressure reading should be taken and the urine passed on the morning of the treatment day should be tested for albumin, at least. This can be performed as part of the minimal medical inspection and is the only means of detecting the threat of eclampsia and intoxications of pregnancy in time to prevent the precipitation of critical accidents by treatment. The patient should not, however be alarmed by the procedure.

Special Tests in Intensive Intravenous Arsenotherapy—Leifer (1940) states that the routine examinations for the control of reaction include (1) daily urinalyses with determination of urobilin (2) determination of the urea nitrogen content of the blood and the icterus index at the beginning and at the termination of treatment, (3) complete blood count, including that of the platelets, at the beginning and at the termination of treatment, (4) darkfield examination of material from all open lesions (5) estimations of renal function by determination of the specific gravity of the urine (6) special tests of hepatic function by the bilirubin method.

GENERAL PRINCIPLES OF TREATMENT OF REACTIONS

The general character of the reaction mechanism in the administration of arsenic and heavy metals makes possible a certain degree of generalization on methods of treatment.

Emergency Aid.—A number of treatment reactions, but fortunately not often the most serious ones, are matters of emergency often to be dealt with in the treatment room, with the patient on the table. In such situations, equipment on the spot, experience, team-work, discipline and speed may save discomfort and even life itself Figure 180 summarizes the equipment of the emergency cart or tray

Detoxification.—The first group of treatment procedures of general availability may be spoken of as "detoxifying measures. These are directed at enabling the body tissues and in some cases particularly the excretory organs to carry the injury inflicted by the poisonous element in the treatment without

sons, even though its evaluation is not complete, it should be routinely used wherever it seems probable that one or other of the drugs mentioned is responsible for reaction or complications.

Calcium.—The wave of popularity which has brought calcium into such therapeutic prominence in general medicine has led to interesting and probably important applications in the control of reaction to antisyphilitic treatment.

Spiethoff and Wiesenack in 1920 employed Afenil" and 10 per cent calcium chloride solution as preliminary treatment in intravenous injection of the arsphenamines and likewise used calcium-containing solvents for the drug Their favorable results in the reduction of toxicity were later confirmed by Stümpke, Jacobsohn, and Sklarz, by Schumacher and most recently by Gerwig Schumacher explains the effect as due to a reduction in the length of time that soluble arsphenamine circulates in the blood stream and an increase in spirillicidal effect. Gerwig, in group of 24 cases, showed that angioneurotic symptoms following injection, rise of temperature, malaise and gastro-intestinal disturbances were particularly favorably influenced by the employment of 10 per cent solution of calcium gluconate, the neoarsphenamine being dissolved in the contents of 10 cc. ampule

The mechanism of action of calcium thus employed is probably complex and not fully understood. At least a part of the effect follows the lines suggested by Frei, Nathan, and Munk, Krowarz, Luithlen, Chiari and Januschke, and Klauder and Brown in influencing the background of anaphylactic reaction, the vasomotor phenomena of arsenical complications and the calcium-potassium balance of the skin in which calcium plays the role of sedative. Jui-Wu Mu (1933) opposes this view Lewin (1927) had suggested increased rather than decreased toxic effects from the use of calcium chloride solution as a solvent.

Our experience accords with that summarized favorably above. In two cases in which suspension of treatment was threatened by pronounced gastro-intestinal reaction, treatment was continued without serious difficulty following the simultaneous administration of 10 per cent calcium gluconate solution with the intravenously injected neoarsphenamine and arsphenamine (606) The pruritic symptoms without dermatitis observed in some patients have also responded very well. In the treatment of the late residues of arsphenamine dermatitis in which the acute phase has passed but an annoying vasomotor instability with scattered outbreaks of dermatitis persists, calcium is very useful in conjunction with ultraviolet light and roentgen-ray The administration of the drug in large doses by mouth (60 to 75 grains of the effervescent lactate or the gluconate twice daily in addition to the intramuscular injection of the 10 per cent solution in 5 to 10 cc. doses) is desirable. The intramuscular injections may be given from one to three times weekly If the drug is given intravenously the rate of injection should be extremely slow to avoid the disagreeable flushing and the possibility of capillary emboli.

Glucose —Glucose as a 40 per cent aqueous solution may be employed both as a buffer and for possible therapeutic and prophylactic effects on the body tissues. Harrison endorses Dreyfus's use of it as a solvent for neoarsphenamine with the provision that the solution be made alkaline by the addition of 4 cc. of 4 per cent NaOH per 250 cc of glucose solution to raise the pH A part of the effect may of course, be due to the alkali but Harrison noted marked reduction in minor reactions in his clinic with the use of this solvent. Harrison stated that in certain German clinics arsphenamine erythemas were treated at the outset by injections of 20 to 30 cc. of 20 per cent dextrose intravenously coincidently with 10 to 20 units of insulin to fix it in

the liver. Loren Shaffer (1934) reported good results in the treatment of post arsphenamine exfoliative dermatitis with glucose intravenously. The course of his cases was materially shortened by this means. The effect of carbohydrate in influencing the liver in arsenical intoxication must be further studied, in view of Craven's and other observations on the bad effects of a high carbohydrate diet. The unfavorable action observed by these workers may be due not so much to the absorbed carbohydrate as to the effect of such diets on toxin production by micro-organisms in the intestinal tract. Glucose in arsenical dermatitis may be used in doses of 20 cc. of the 50 per cent solution once or twice a day.

Venesection.—This half-forgotten method of dealing with acute intoxications deserves reconsideration. Harrison mentions it (withdrawal of 500 cc. of blood from cubital vein) in convulsive reactions following arsphenamine, and it should be tried in conjunction with the administration of Fischer's solution in acid arsphenamine accidents and supposed eclamptic seizures.

Influence of Detoxification on Therapeutic Effect.—It is very proper to raise the question as to whether the use of detoxifying agents as prophylaxis either in solutions for making up the arsphenamines or when separately administered, has an effect in reducing the therapeutic action of the drug. While in the main, the existing evidence is against any such action the question is unsettled. Voegtlin and Dyer, Citron and others showed that the spirillicidal action of the arsphenamines is unimpaired by sodium thiosulphate. Calcium and glucose have no impairing effect. Vitamin C has no deterrent effect on therapeutic action.

Other Detoxification Methods.—Mention has already been made of vitamin C and its derivatives for detoxification of the arsenicals (diet, etc.). Innumerable other substances have been proposed for the same purpose (Doak 1941). Among the more important are: degradation products of protein (amino-acids) (Rebaudi, 1934; Bensch, 1933); and sodium dehydrocholate (decholin) (Jacchia and Truffi, 1934; Shaw, 1930; Appel and Jankelson, 1936; Kolmer, 1940).

Protection of the Liver Cell.—The influence of diet has been discussed and it may again well be emphasized that the clinical good effects of the use of glucose intravenously are not necessarily to be confused with the unfavorable effects of a high carbohydrate diet. The belief that hepatic injury plays an important part in other types of arsphenamine reaction than jaundice and acute yellow atrophy and can be prevented or compensated by administering liver extract has been experimentally studied by Milbradt and applied clinically by Spiethoff. By blocking the reticuloendothelial system of the rabbit, which threw the entire load of the subsequently administered arsphenamine on the liver, Milbradt showed that the administration of liver extract protected the treated animal against the severe intoxication which ensued in the untreated. He experimentally related this form of protection to the prevention of dermatitis by sensitizing white rats to neoarsphenamine and protecting certain of them against cutaneous sensitization eruptive manifestations by liver extract (Hepatrat). Spiethoff reported excellent results in arsphenamine and heavy metal poisonings, including exfoliative dermatitis in the course of treatment, from the subcutaneous or intramuscular use of this liver preparation and regards its use as a form of substitution therapy, though the response obtained in psoriasis suggests a nonspecific protein phase. MacKee and Astrachan (1940) found liver extract (Parke Davis and Company) useful in various manifestations of arsenical intolerance, using a dosage of 2 cc. intramuscularly given either just prior to the arsenical injection or in courses of 12 injections at the rate of three per week, in cases of established intolerance.

Change of Drug.—It has been shown that reacting patients tend to react more than once. In some patients this tendency is so pronounced that it is impossible to overcome it by the ordinary preventive and treatment pro-

cedures appropriate to the particular type of reaction. In such cases modification of the treatment regimen by a change of drug becomes the only method of dealing with the situation. Nitritoid gastro-intestinal and cutaneous reactions particularly fall into this category A shift from arsphenamine to neoarsphenamine or from neoarsphenamine to bismuth arsphenamine sulphonate a shift from arsphenamine (606) alone to half doses of neoarsphenamine and bismuth administered simultaneously a shift from an arsphenamine to bismuth alone as a result of inescapable intolerance or a shift from any of these preparations to mapharsen are typical examples of the devices that must be used In latent and late syphilis the consequences of such a shift are easier of adjustment than in early syphilis, where depriving the patient of the benefit of an arsphenamine may lead to serious consequences in relapse neurorecurrence or during pregnancy in the infection of the child Before a shift is made detoxification by the various general methods should have been attempted and only when this fails should a method of less intrinsic effectiveness be adopted.

Preparation and After-care.—Considerations involving the preparation and after-care of patients for arsenical and heavy metal therapy (not including tryparsamide which is separately considered on p 1042) are outlined from the standpoint of instructions to the patient in Fig 179

Fever —The patient s temperature should invariably be taken as a preliminary to any form of intravenous therapy As a complication of treatment for syphilis fever may be a manifestation of therapeutic shock (Herxheimer effect) or occur as part of cutaneous and other reactions. As a solitary symptom it may occur occasionally as a slight afternoon rise of temperature in the course of mercurial treatment, possibly due to lighting up of a focus of infection "ninth day erythema" or to the syndrome of bismuth grippe, conditions usually accompanied by arthralgia and malaise with some gastro-intestinal disturbance. After arsenical administration fever is usually accompanied by other symptoms but it may be the only reaction to an arsenical given intramuscularly in patients in whom there is no reason to suspect either a Herxheimer effect or a local abscess. It may be a symptom of embolism in some silent structure such as the central portion of the lung or the spleen. In intensive arsenotherapy fever especially when associated with an eruption, is an extremely common reaction symptom ("secondary fever" 64 per cent with neoarsphenamine 12 per cent with mapharsen in the five-day drip arsenotherapy) It also occurs as an important evidence of intolerance in eighteen and twelve week mapharsen systems. As a rule, however the occurrence of fever as a definite and protracted reaction in treatment for syphilis should stimulate an immediate search for an intercurrent infection, especially a tuberculous focus which may have been present and unrecognized before treatment began or which may have been stirred up by the treatment. Malaria should be looked for in Southern patients.

The importance of the taking of patient temperature before giving an arsphenamine treatment, in order to be fair to the drug as well as the patient, is well illustrated by the case of seemingly healthy child ith tuberculid bom one of us (J H S.) as asked to treat with arsphenamine for nonspecific effects. The child entered the hospital, rosy-cheeked specimen of healthy girlhood, and was ready to be taken t the treatment room when it was found that her temperature as 101 F Treatment as not given, and some four months later she died of miliary tuberculosis. If she had received the injection of arsphenamine the drug would, of course, have been held responsible for lighting-up of the tuberculous focus and the fatal issue. Fever in syphilis is, in our experience, one of the first symptoms t disappear under arsphenamine treatment.

Water errors may be the cause of chill with fever as a treatment reaction and usually affect a considerable number of patients in a group This reaction may follow sodium iodide administration intravenously when either drug or solvent is impure. The tubing reaction (see p 392) is another source of sharp febrile reactions in groups of patients under treatment.

On one occasion on the Mayo Clinic service it was noticed by the operators that showers of reactions occurred on Mondays. Part of it was undoubtedly due to haste in injecting but the reactions did not finally disappear until after it was discovered that water that was distilled on Friday and Saturday was being kept over by an inexperienced attendant and supplied to the operating rooms on Monday morning without redistillation.

In the matter of pretreatment preparation of the gastro-intestinal tract, wide differences of opinion have existed Particularly where "606" is used and on services operating under pressure with an expected high incidence of reactions, *an outright preoperative preparation* with a cathartic and a fasting stomach throughout the treatment day was advocated by British base hospitals during World War I Lees, on the other hand disapproves. A very light meal (tea and buttered toast) before and a moderate food intake after treatment has seemed to us satisfactory O'Donovan has insisted that no one should undertake the treatment of syphilis without having immediately available, facilities for the hospitalization of the reacting patient, and this we believe is in general true. When emergencies occur the delay in serious cases may be sufficient, as in acid arsphenamine administration, to cause loss of life. The average requirements for emergency use in the after-care of reacting patients are outlined in Fig 180

THE SPECIAL REACTIONS AND COMPLICATIONS. DESCRIPTION AND TREATMENT

We return now to the general clinical classification of reactions (Fig 174) for the special application of general treatment principles and additional special methods.

Blunders (1)—Acid Arsphenamine.—The most terrifying and often the most unpardonable of blunders in the use of the arsphenamines is the administration of concentrated unneutralized arsphenamine (606) in place of neoarsphenamine.

Not a year passes that this accident does not occur often in a well-managed clinic or hospital rather than in the office of the inexperienced practitioner One of us (J H. S.) has, on one occasion, been caught by a nurse on the verge of doing this very thing The consequences stand out like a lighthouse not only to operator and staff but to the newspaper-reading public, which thereupon promptly damns the modern treatment of syphilis without further thought or discussion. The prevention of this accident on syphilological services can be accomplished only by the most unceasing vigilance, and no chief ever feels himself entirely free of the anxiety which some of his less experienced associates and assistants may suddenly and without warning convert into an agonizing reality Much can be accomplished by training every hospital intern to read labels systematically in advance of the preparation of any drug by insisting that no package of arsphenamine (usually plainly marked) shall be opened or prepared for opening except in the presence of the operator that the label shall be kept attached from start to finish and no preparation ever made up from an unlabeled ampule that the business of mixing arsphenamine, like that of steering a ship, should be governed by the rule "Don't talk to the man at the wheel" and by the thorough drilling-in of the rule that any arsphenamine preparation which does not completely and almost immediately dissolve in 10 cc of water is to be thrown out. The label can be kept attached by a rubber band, even with heat sterilization of the ampule and the solubility of "606" in the vast majority of preparations is such that there is at least a very definite retardation if not

an absolute refusal to go into complete solution in this amount of water This fact should at once arouse suspicion. Only experts can be relied upon to distinguish the two drugs by their color and odor To prevent the *administration of diluted but unneutralized arsphenamine, which* fortunately is less dangerous than the administration of concentrated arsphenamine solution, a drop or two of phenolphthalein (alcoholic) solution added to every bulk solution of an arsphenamine to turn pink on alkalinization, is a very useful protection devised by Chambers.

The symptoms of acid arsphenamine administration depend on the concentration of the solution. With concentrated arsphenamine administered at the rate too often customary for neoarsphenamine, almost nothing may happen for the first few seconds to a few minutes. The patient may even rise from the table, don his clothing, and proceed to the corridor or the street before death overtakes him. A complaint of agonizing pain in the arm and in the small of the back, choking sensation, collapse or syncope and death before any assistance can be rendered is the usual rule. When the dilute solution has been given at a slow rate, symptoms usually begin to appear before the first decigram is administered. The complaints are identical with those in the case of the concentrated solution and the general effect essentially the same but fortunately more retarded and less often fatal. Suspicion should always be instantly aroused by any complaint on the part of the patient of pain in the back during an injection, and of pallor or the appearance of collapse instead of the scarlet flush of a beginning nitritoid reaction. Suspension of both radial pulse and respiration may occur so that the patient seems dead This reaction is indistinguishable from true arsphenamine collapse following the use even of a properly prepared preparation.

If the patient who receives acid arsphenamine is not dead when reached, a determined fight should be made for his life. When dilute acid solution has been administered, the outlook is excellent if alkalinization with Fischer's solution (p 387) intravenously is immediately employed. Intracardiac adrenalin and artificial respiration may keep the patient alive long enough to permit of its administration. Adrenalin should also be given intravenously if the heart is still acting. In two instances of arsphenamine collapse of the idiosyncratic type the determination to fight the case by these methods saved the patients lives. After the fourth hour anuria is apt to be recognized in patients who have not been completely alkalinized by vein. It will respond usually only to the use of Fischer's solution and large amounts of alkali by mouth, and per rectum. Warmth and supportive measures are, of course indicated.

Blunders (2)—Toxification of Drugs.—This has been to some extent discussed under technic. The shaking and aeration of neoarsphenamine in the process of preparation undoubtedly is responsible for a great deal of everyday trouble (see p 299) (*cf* mapharsen) The relative instability of neoarsphenamine demands, moreover that the preparation be kept in the dark and in an ice-box (which it seldom is) even by the distributor after it leaves the manufacturer Dissolving arsphenamine (606) with hot water and administering it immediately after preparation, increases the toxicity

Blunders (3)—Hurry and Speed.—The great toxifier of most intravenously administered medication is speed in injection, as has been repeatedly emphasized. The atmosphere of hurry is fundamentally inimical to the reactionless treatment of syphilis and must be systematically discouraged in office and clinic When even the busiest physician enters his treatment room he must leave behind for the moment all preoccupation with other patients and the affairs of his office and in a leisurely and premeditated fashion follow an exact routine to the completion of the treatment. The rates of injection appropriate to the intravenously administered arsenicals are given on page 269

Blunders (4)—Water Errors.—These have been discussed on page 268 Chills and fever occurring in crops among the patients given treatment on a certain day or following the administration of a drug not usually producing such reactions, warn the head of a service that technical exactitude is not being fully satisfied on this point.

Blunders (5)—Tubing Reaction.—These reactions occur in crops with a quite typical symptomatology This type of reaction must be specially guarded

against in the apparatus used for intravenous drip therapy They are due to a toxic substance soluble in weak alkalis, present in rubber vulcanized by certain methods associated with an excess of sulphur The substance is removable from new tubing by soaking in 5 per cent NaOH solution for twenty-four hours. The reaction was described by Busman and Stokes and was evidently an occasional source of "trouble epidemics" in the First War In from thirty minutes to an hour after injection an increasing weakness with aching of the legs and back is noted followed by a chill, often of great severity The chill may be the first symptom Nausea and vomiting occur with violent cramplike pain in the lumbar region and diarrhea with tenesmus. Headache is intense and with repetition of the rigor there is a sharp rise in temperature the fever reaching from 102° F to 103.5° F accompanied by varying emotional disturbance and prostration Patients frequently laugh and cry hysterically The temperature then usually declines to normal within eight hours but the fever may persist for two or three days and the headache, backache, gastro-intestinal disturbance and prostration may persist for several days to a week. A profuse crop of herpes often follows the reaction. We have seen one case of jaundice but no renal complications. Considering the extremely pronounced and unpleasant character of the symptoms, recovery in robust persons is rapid and complete.

It is conceivable that the reaction in the debilitated or when coupled with Herxheimer effect or an intolerance of arsphenamine, might have serious consequences. What was apparently fatality from this cause was reported to one of us (J H. S.) by physician after the publication of Busman and Stokes observations. Busman developed a leukocytosis of 14,600 with 91 per cent polymorphonuclears at the height of the fever while Stokes had white count of 9600 with 82 per cent polymorphonuclears Both urines were normal. The pulse is likely to remain rapid for several days. Important symptoms may fail to appear or may assume unusual severity The general features of the reaction, however run so true to form both in man and dog that they suggest the toxic action of definite poison, possibly one of the mercaptans, since the reaction seems to occur chiefly in sulphur vulcanized tubing In large hospital services the reaction can usually be recognized as group affair involving considerable number of patients whose course under treatment has been previously uneventful. Guy in his report of reactions at Camp Travis, describes group of complications of unknown cause affecting 33 patients treated in single forenoon, which was identical in all respects with the tubing reaction. Even after the publication of Stokes and Busman s observations, group of tubing reactions appeared on the Mayo Clinic service following the advent of an inexperienced nurse.

The tubing reaction requires only symptomatic treatment, the recovery usually being uneventful.

Blunders (6)—Embolism.—Embolism must be regarded as a blunder at least in intravenous work, though the explanation may fail to materialize. Agglutination of red cells in speed shock may conceivably induce embolic effect. Clearing a plugged needle by running a stylet through it while the point is still within the lumen of the vein is another known source of embolism. Air embolism, often feared, is in our experience a trifling matter for it is remarkable what amounts of air can pass into the cubital vein without symptoms of any sort from the patient, albeit with impending nervous collapse on the part of the inexperienced operator who sees the bubbles go through the glass telltale too late to shut them off While proper attention to filtration is necessary Loren Shaffer undertook to inject intravenously in rabbits fluids containing considerable amounts of suspended cotton fibrils and so forth without at any time producing symptoms suggestive of embolism. Breakage of a needle within the lumen of the vein with lodgment of the fragment in the heart has

been said to occur In all probability the larger part of the symptoms even remotely suggestive of pulmonary embolus including pain in the side, pain in the chest and dyspnea following intravenous injections (6 in 6500 injections) is due to agglutination thrombi due to too rapid injection rates Shivers finds that precipitation of all the arsphenamines occurs in the blood *in vitro* at a pH below 6 4

Small pulmonary emboli should be symptomatically treated by rest in bed and local topical applications if signs of pleurisy develop. Pneumonia may ensue. It is not always advisable to silence the cough. Cerebral emboli are usually fatal. Emboli in other structures may give no signs except perhaps localized pain and a slight rise of temperature, their identification as emboli being therefore only speculative and *post hoc* Burns and Bromberg have reported a fatal case of cerebral embolus following the injection of arsphenamine in a woman of fifty-one in which the clinical symptoms suggested hemorrhagic encephalopathy and the gross autopsy appearances seemed to confirm the diagnosis. On microscopical examination however multiple fat emboli were found in the brain kidneys and lungs.

Following intramuscular injection, emboli may occur with or without fault in technic. A violent fit of coughing beginning while the patient is still on the table or shortly after he rises, is the commonest sign. In some cases syncope may occur and cerebral embolus may be fatal Technical factors are subsequently discussed.

Local Arterial Embolism —Arterial embolus into the skin following insoluble intramuscular injections gives rise to a very characteristic group of symptoms, according to Freudenthal who reported the first observed cases from Jadassohn s clinic, and Gammel who reported the complication in the American literature. It occurred, in Gammel s experience, five times in 45 000 injections. From a few minutes to a few hours after the withdrawal of the needle through which an insoluble bismuth or mercurial preparation (or other than antisyphilitic drugs, Sulzberger and Baer 1940) has been injected the patient complains of pain often severe and usually radiating down the leg The buttock swells rapidly the infiltration appearing more superficial than the deep resistance of abscess formation. There may be symptoms referable to nerve injury such as a dead feeling in the foot, in the bladder region and so forth and in 4 of the reported cases the symptoms of peroneal paralysis have appeared. Freudenthal gives it as highly characteristic that the symptoms are not only local as in irritation dependent on the site of injection but that the patient feels sick all over" and may have fever If the arterial tree is involved at the proper point, lesions of the bladder and vagina may appear The highly characteristic external manifestation is the retiform network of a bluish color which forms over the buttock from the eighth hour to the first or even second day There may be a slight tendency to gangrene in the darkened meshwork or massive gangrene of the rectum bladder penis scrotum and vagina may occur as reported in Gammel s and Kimberly s (1938) cases, for example

The process must be distinguished from local anaphylactic reaction to bismuth in which there is swelling and edema of the buttock but no network and no referred pain deep abscess which is much slower in developing, not usually accompanied by constitutional symptoms, and presents only deep induration without referred pain and deep hematoma which does not give rise to the retiform network, gangrenous changes and constitutional reactions

The milder examples of arterial embolism recover uneventfully on rest and

hot applications. *If gangrene occurs, the slough must be allowed to separate* or be surgically removed (Gougerot) The very slow granulation resulting from the impaired blood supply would, one might expect, be stimulated by the use of sulphhydril (Sulfen) Nerve injury if it occurs, recovers quite slowly and there may be residual paralysis.

The prevention of this unfortunate accident is not wholly dependent on the aspiration technic advocated on page 305 in intramuscular injections. Gammel points out that an attempt to aspirate through a small needle filled with a heavy emulsion will fail to detect the presence of a needle point in a vessel and that emboli of this type may also result, when the injection is given into the wall of a vessel and not into the lumen proper (Freudenthal) Gammel recommends as special precautions either the use of an empty needle, which is aspirated by a separate syringe before the syringe containing the emulsion is attached, or the use of a needle proportionate in size to the heaviness of the emulsion, the largest sizes being used for the heaviest emulsions. In any case, it is impossible absolutely to insure against the occurrence of this accident and this point should be borne in mind in medico-legal considerations.

Infection —The occurrence of systemic infection from unclean technic must be excessively rare. It may however result from the neglect of certain considerations other than those of mere asepsis. The lowered resistance of diabetic patients and their susceptibility to pyogenic infection, or of elderly patients in a cachectic condition may lead to meningeal infection by passing through infected tissue in entering the spinal canal or following even the proper injection of an intramuscular suspension. Infections of the meninges may follow the withdrawal of spinal fluid in patients with a septicemia, which emphasizes the great importance of the detection of intercurrent infections prior to any such procedure in treatment work. The mere presence of pus in a localized abscess after intramuscular injection does not prove infection nor does the grumous bloody fluid that may occur from the saponification of a bismuth compound in the tissues with swelling of the buttock and localized tenderness indicate infection or poor technic. The remarkable safety factor involved in all manipulations in which blood and blood serum are concerned is nowhere better illustrated than in intraspinal therapy in which, in spite of a technic that can be only relatively aseptic in the bacteriological sense because of the impossibility of complete sterilization, infections are rare (1 in 10 000 injections, in our experience) In procedures involving the treatment of patients with donors serum the possibility of transfer of infection must be considered

THE CONTROL OF COMPLICATIONS IN TECHNICAL PROCEDURE

Needle Complications.—In Figs. 181 and 182 are tersely summarized the prevention and management of that highly disagreeable and sometimes serious group of accidents due to needle breakage. Their technical importance is, like the function of the stable door less often thought of before than after

Intramuscular Injections.—In the technical description of intramuscular injection procedure, the impression might be gathered that uniform smoothness of performance is the rule. In Figs. 183 184 and 185 are summarized the preventive and treatment aspects of the complications of this technical procedure. Forethought, asepsis, inspection, placement, aspiration, and massage make up the "art" of intramuscular injection Forethought inquires into the results of the previous treatment and the condition of the tissues especially

Multiple nodules mean accumulating drug or poor technic and vehicle. Edema and tenderness with orange or grapefruit-like masses in a large, fatty buttock, may mean abscess formation, cystic accumulation or saponification (Barthelmy) Abscess may be entirely asymptomatic and point only after several weeks or even months or it may require evacuation within a few days. Hem

Fig 181

TO PREVENT NEEDLE BREAKAGE

1 Use only the latest nonbrittle noncorrodable steels. Watch for inferior material and workmanship in wartime
2 Have the needle point sharp.
3 Never jab or force against an obstacle
4 Test needles for condition especially if used with corrosive drugs (Hg soluble) (Fig 105)
5 Guard against sudden movement of the patient whether of back, muscle twitch, etc. Explain to him what is about to happen.
6 Guard the holding hand from sudden movements (pp 305 323)
7 Never introduce a needle all the way to the hub Leave at least ¼ inch exposed.
8 Avoid changing hands on syringes with needles fixed in tissue.

atoma and suggillation give rise to no serious difficulties. The discoloration is not retiform or netlike but diffuse and "black-and-blue" fading to yellow An infiltration is not necessarily below the needle point but may appear at the outer edge of the buttock. Diffuse gradual fibrosis (fesse de bois of the French) produces at first a doughy rubber-ball firmness, ultimately with a

Fig 182.

IF A NEEDLE BREAKS

If an intramuscular needle breaks:
1. Silence. Admit no blame. Stub and syringe kept out of sight.
2. Keep left hand in place. Feel lightly for fragment if broken near surface (hub)
3. If not felt, let go with hand.
4. State facts to patient after reflection, witness present.
5. Sometimes worth while to try to recover fragment through small incision under local anesthesia. Only if palpable in the skin.
6. Take patient to roentgenologist and surgeon for visualization, plates (2, 90 degrees) and removal of fragment.
7 I moving, avoid all weight or pressure on site.
8. Keep the fragments as recovered, with the hub and plates.
9. Write full account into the history t nce.
10. Notify insurance protection Move f release only on their advice.
11. If spinal needle breaks, proceed bove but
 ( ) Maintain patient' posture on table. Keep spine sharply flexed.
 (b) Do not lose the puncture site in local sterilization. Mark and note landmarks.
 ( ) Call the surgeon to the case
 (d) A oid crushing the needle ith hemost ts

woody or almost gritty fibrosis on pa ing the needle and a return or leakage of the injected su pension.

Placement into any but the upper outer quadrant may give rise to nerve injury as in Gammel's case of peroneal nerve injury by a medical student. Freudenthal points out that injection toward the outer in tead of the inner part of the outer quadrant is more likely to m ol e the arterial plexu *in local em-*

bolism. Aspiration and the selection of a needle large enough to pass easily a suspension of the viscosity employed will reduce emboli to the lowest terms. A fluid vehicle given through too large a needle may cause leak-back with infiltration. Massage is discussed on page 307

Technical Trouble in Intravenous Injection Causes and Treatment.—For purposes of condensation and reference the causes and treatment of primarily technical difficulties in intravenou injection are described under the following seventeen heads

1 **Pains at injection site during injection** Caused by (*a*) dull, overlarge or lacerating needle which strips vein (*b*) striking a "pain per

Fig 183.

TO AVOID TROUBLE IN INTRAMUSCULAR INJECTION

1 Use noncorroding needles.
2 Test by bending strain at frequent intervals (Fig 103)
3. Insist on asepsis (by boiling of instruments, p. 256 *et seq*)
4 Warm and shake suspensions thoroughly (p 301)
5 Be sure solubles are completely dissolved.
6. Question the patient before injection (p 381)
7 Palpate the buttock for nodes, tender spots, fluctuation.
8. Inspect the mouth nd skin.
9 Introduce clea needle no drug on the outside Empt needle or large-bore needle for heavy suspensions.
10. Be quick but don't jab. Watch corsets.
11 Use long enough needle for fat patients (p 293)
12 Use the upper outer quadrant of the buttock (Fig 181)
13. Aspirate by pulling back on the piston after introducing the needle Count 10 slowly (Fig 168)
14 Inject slowly
15 Hold needle in place one minut after injection.
16. Utilize valve action t prevent leak-back by pushing skin and subcutaneous tissues upwards after needle is ithdrawn (for thin suspensions and solutions)
17 Massage site one t three minutes or more
18. Have patient exercise his gluteal muscles after treatment.
19 Insist on hot sitz bath and massage daily (p 383)
20. If needle breaks—be silent and see Fig 182.

FORETHOUGHT ASEPSIS, INSPECTION PLACEMENT ASPIRATION MASSAGE MAKE UP THE ART" OF INTRAMUSCULAR INJECTION

ception point (*c*) leakage of irritant solution (*d*) striking or impaling a nerve (median) (*e*) hematoma

Treatment ( ) hold needle still without torsion or ten ion, while injecting (*b*) use local anesthetic (see p 312) ( ) stay within antecubital space if possible (*d*) avoid injection of deep structures out of sight and feel (*e*) secure full return of blood before injecting

2 **Perivenous tissue infiltration** Caused by ( ) nonentry (*b*) partial entry (see Fig. 134) (*c*) vein tear (*d*) bstruct on of thin-walled vein above site (*e*) injecting through a hemat ma.

Treatment: ( ) stop (*b*) inquire (patient may think it *should* hurt) ( ) withdraw (*d*) choose new site elsewhere and complete injection (to avoid sensitization) ( ) cold wet compress or ice-bag—after

twenty four hours hot magnesium sulphate solution compress (f) local or intravenous injection of sodium thiosulphate solution, if

Fig 154.

TREATMENT OF INTRAMUSCULAR INJECTION COMPLICATIONS

1 For prevention, see Fig 153
2 Palpable induration or pain.
 ( ) Question correctness of site
 (b) Avoid node or change buttocks.
 ( ) Both sides involved—consider postponing
 (d) Paint sit with tincture of iodine (if no skin irritability)
 ( ) Inquire int nd insist on sits bath, heat nd massage
 (f) Massage more thoroughly after injection
 (g) Reduce dosage especially for first 4 injections I patient ho has had no intra muscular treatment.
 (h) Increase local anesthetic if used
 (i) Cha ge t another preparation.
3. Twinge down leg.
 ( ) Change site before injecting (farther up and out)
4 Pain down leg.
 ( ) Question sit of injection
 (b) If pronounced, skip one treatment or change side
 ( ) Heat, salicylates by mouth, baking infra-red radiation
 (d) Look for other causes of sciatica, especially focal infections.
5 Aspiration yields fresh blood.
 ( ) Withdraw needle without injecting Choose new sit 2 cm. ay Preferably change sides.
 (b) If much blood, use fresh needle fresh drug
6 Aspiration yields pus (or old bloody fluid)
 ( ) Silence t the patient.
 (b) Leave needle in, ttach fresh syringe aspirate as much as possible
 ( ) Hot pplications and expectancy Absorption is the rule
7 Severe suggillation, cutaneous embolus.
 ( ) Absolut rest N massage.
 (b) Ice-bag. Later hot compresses.
 ( ) Morphine.
8 Drug leaks back.
 ( ) Smaller bore needle
 (b) Hand valve action.
 ( ) Keep needle in place one minut
 (d) Massage
 ( ) Hot pplications and sits bath
 (f) If buttock fibrous, suspend tre tment
9 Systemic embolus
 ( ) Bed, quiet, ice-bag symptomatic treatment.

much edema or necrosis threaten (g) massage baking, pas ive movement.

3 **Necrosis and slough** Caused by (a) large amounts or concentrated alkaline 606" or "914" (b) other alkaline solutions (Fischer s)

Treatment (*a*) ice-bag, later heat (*b*) dry treatment until slough is defined (*c*) piecemeal excision (*d*) sulphhydryl wet dressings (*e*) massage, electric light exposures, baking passive movement.

Fig 184.

TECHNICAL TROUBLE IN INTRAVENOUS INJECTION

1. Pain at injection site.
2. Perivenous tissue infiltration.
3. Necrosis and slough.
4. Hematoma.
5. Suggillation and subcutaneous hemorrhage.
6. Pain in shoulder or arm during injection.
7. Vein spasm.
8. Thrombophlebitis (acute).
9. Thrombophlebitis (chronic, local)
10. Entering an artery
11. Broken needle.
12. Bleeding puncture.
13. Discoloration of site.
14. Puncture tattoo.
15. Injecting median nerve.
16. Cutting down on vein.
17. Speed shock.
18. Embolism.

EVEN THE BEST OPERATORS HAVE ACCIDENTS

4 Hematoma Caused by (*a*) transfixing of vein (complete puncture of opposite wall) and partial withdrawal (*b*) withdrawal after entry but no return of blood (plugged needle or transfixed vein) (*c*) torn vein (thin wall, dull needle) (*d*) leaving tourniquet on after withdrawing needle.

Fig 185 —Slough following the injection of neoarsphenamine int the subcutaneous tissue The entire arm from below the elbow to above the middle of the biceps is brawny and the elbow is immovable Evidently almost the entire dose of concentrated solution had been delivered outside the vein.

Treatment compression bandage at site, elevation of arm when bleeding stops, cold compress. Complete the injection elsewhere.

5 Suggillation and subcutaneous hemorrhage Caused by (*a*) blunt needles which tear or round instead of pointed needles which, in

stead of puncturing, cut (b) too large needle (c) thin veins (d) no compression on withdrawal (e) blood dyscrasia.

Treatment (a) pressure bandage (b) reassurance (c) better technic (d) hypodermic needles (26-gauge) in syringe technic.

6 Pain in the shoulder or arm during injection Caused by (a) hyper alkaline "606" (b) other irritant solutions (c) vein spasm (q v) (d) slow injection of mapharsen

Treatment (a) quantitative alkalinization (b) slower rate or intermittent injection (c) salt solution 0 6 per cent as solvent (see p

Fig 187 —Result of injecting the median nerve with arsphenamine, mistaking it for vein (patient right arm) *The unhealed slough, nearly year old, can be seen above the inner condyle* There is distinct trophy of the muscles, loss of power in the hand, atrophy of thenar eminence, and trophic ulcer on the anesthetic index finger

260) (d) slapping lightly over vein (spasm) (e) hot applications (f) calcium gluconate solution, 10 per cent 10 cc. by very slow intravenous injection just before treatment (hypodermic needle) (g) injecting mapharsen rapidly

7 Vein spasm Caused by (a) idiosyncratic hypersusceptibility (b) other causes as for pain (above)

Treatment (a) as for pain (b) change of drug

8. Thrombophlebitis (acute) Caused by (a) idiosyncrasy (b) alkaline or irritant solution (c) slow injection of mapharsen Symptoms (a) pain at time of injection or spasm (b) tenderness, slight redness bruise discoloration along vessel (c) closure in four to seven days

(d) fibrous bluish-white cord thereafter or may reopen, but vessel rarely usable again.

Treatment Usually none Hot compresses.

8a. Thrombophlebitis (chronic) Caused by repeated injections into same vein, with slow cordlike obliteration or nodosity at site.

Treatment alternation of veins, saline solvent, drug-change good technic.

9 Entering an artery Caused by aberrant course of brachial artery Symptoms: spurt of bright blood or syringe piston forced out of barrel.

Fig 186.

PREVENTION OF SPINAL PUNCTURE REACTION

1 Know in advance that no increase in intracranial pressure exists (symptoms of headache vomiting, and finding of choked disk)
2. Take temperature and inquire for symptoms of respiratory and other infections.
3. If any trace of blood appears, keep patient in bed for twenty-four hours.
4 Use relatively small needle (21 or 22-gauge)
5 Take pressure with manometer if possible Normal for Hg 7 12 mm., for water 100–180 mm.
6. Allow fluid to drip very slowly Never aspirate (A flow of 1 to 2 drops second is safe)
7 Give sedative (codeine, 1 grain hypodermically or sodium amytal 3 to 5 grains thirty to forty minutes before puncture) with dose to take home.
8 If ambulatory have patient rest one hour on stretcher face down, then go home until next morning.
9 Patients who return to heavy work do so at their own risk.
10. If rest can be secured, four to six hours sleep after puncture is advantageous.
11 Patient may go to stool or urinal. No straining If unable to pass urine report by telephone.
12. Report pain in legs, weakness, stiffness, spasticity fibrillary twitchings, by telephone
13. If headache develops, lie down, have someone report by telephone Remain quiet, foot of bed elevated forty-eight hours.
14. Mild saline cathartic day following puncture if constipated
15 No rough jouncing travel, forty-eight hours.
16. Medullary block (abrupt cessation of respiration) and hemorrhage symptoms may be *delayed six to twenty-four hours. Report as under 13.*
17 Recent, as yet unevaluated, observation suggests that reaction may actually be prevented by exercising the patient or allowing him to be active after lumbar puncture. Not yet recommended.

Treatment withdraw if using gravity method, inject if not. Compression over puncture two to three minutes.

10 Broken needle (See p 396, Fig 182)

11 Bleeding puncture Caused by entering skin and vein in same movement. See also No. 5

12. Discoloration of site (permanent) Caused by (a) perivenous leakage of certain drugs such as colloidal mercury sulphide, silver salts (local argyria) gold salts.

13 Puncture tattoo Caused by: (a) droplet of colored solution on needle when entered (b) rusty needle or corrosive solution ($HgCl_2$)

14 Injecting median nerve Caused by (a) technical ignorance (b) hit or miss probing out of sight or feel. Symptoms (a) twinge and pain down arm to fingers (b) later atrophy etc. (see Fig. 187)

Treatment as for (9)

15 Cutting down on vein unnecessary in present-day practice
16 Speed shock Caused by (a) inexperience (b) hurry See page 244
Symptoms nitritoid reaction gastro-intestinal reaction etc.
Treatment See page 410 small needles, timing device, vigilance.
17 Embolism Caused by (a) "ramming" a plugged needle with a stylet while in vein (Baketel) (b) "mauling" a fat arm or leg with a

Fig 189

TREATMENT OF SPINAL PUNCTURE REACTIONS

1 Headache (and nausea)
(a) Prevention (see Fig. 188)
(b) Reassurance
(c) Lie down without pillow The headache stops.
(d) Remain lying down (in bed) twenty-four to forty-eight hours. (No attempts to rise to see if "it is passing off")
(e) Quiet.
(f) Foot of bed elevated 6 to 10 inches.
(g) Patient fed lying down.
(h) Enema or mild laxative as needed.
(i) If headache does not pass off on lying down, seek other explanation—most often rheumatic or indurative headache with occipital stiffness and localized tender points relieved by infra-red radiation and massage
(j) If patient must be up, or after second day in bed, give capsule of phenacetin 3 grains, acetylsalicylic acid 2 grains, caffeine (stimulant) or sodium bromide 3 grains (sedative) as indicated every two to four hours.
(k) Failure to clear the bowel after puncture may result in nondescript headache
2. Retention of urine
(a) If longer than twelve hours, and no pain, twitchings, altered reflexes, or other signs, allow use of stool Take temperature
(b) Avoid catheterization. Try hot packs, posture etc
(c) In lower cord tabes and myelitis symptoms may not be noted for several days.
3. Stiff back.
(a) Reassurance
(b) Heat or infra-red radiation.
(c) Capsule as for headache
4. Hemorrhage
(a) If early warnings, ice-bags, absolute quiet morphine
(b) Laminectomy drainage if level signs high
5 Meningitis (infectious).
(a) Diagnosis by fever leukocytosis, lack of level signs (extensive process)
(b) Puncture for diagnosis. Coincidently meningococcus serum intraspinally
(c) Double puncture drainage and lavage
(d) Forced drainage—hypertonic saline intravenously with spinal drainage (Kubie-Casten)
(e) Neurological consultation.
6. Traumatic neurosis ("railway spine")
(a) Eliminate organic possibilities.
(b) Reassurance and firmness.
(c) Galvanism and other treatment for hysteria

blunt needle and tearing the vein (c) acid arsphenamine (d) severe nitritoid (see p. 410)

Prevention and Treatment of Spinal Puncture Reaction.—We have attempted to summarize the prevention and treatment of spinal puncture reaction in Figs. 188 and 189 for convenience of reference The technic appropriate to these considerations is given on page 518

Pseudoreactions.—These include indurative headache and stiff neck not relieved on lying down and due to the so-called "rheumatic" torticollis or fibrositis. The identification of the characteristic tender nodes in the nuchal and suboccipital region is seldom difficult and the response to infra-red radiation and massage usually good. Hysterical puncture headache with rigidity of the neck when the canal has not even been entered, has occurred in our experience and responds to suggestive therapeusis and reassurance.

DRUG REACTIONS AS SUCH

The Mouth.—The mouth is one of the most important structures in the whole reaction field. Some form of involvement of it occurs with varying frequency from all the drugs used in the treatment of syphilis, being most frequent with mercury and bismuth and least so with iodide. Mouth reactions are not necessarily a symptom of overdosage, as is often supposed, but may be an expression of idiosyncrasy, especially to arsphenamine and iodide. The appearance of mouth lesions, diffuse or localized, is not to be looked upon as an isolated phenomenon but as part of the systemic toxic reaction to the drug in question, to be dealt with as a symptom of general reaction rather than as a merely local phenomenon. On the other hand, as in all manifestations of intolerance, the weakest point of resistance yields first, and by proper prophylaxis may be bolstered up to carry a heavier load for the sake of the general therapeutic end in view.

Properly heeded, the mouth together with the skin furnishes early warnings of a number of the gravest complications in the treatment of syphilis. It is inexcusable to allow the ordinary case under treatment to reach the extreme degrees of reaction. For that reason we have included weekly inspection of the mouth in all preventive suggestions and have summarized in Fig. 190 the warnings which the mouth gives of impending or actual trouble, together with associated groups of symptoms arranged under the drug from which they may be expected.

It is impossible to escape the impression gained by comparing the course of numbers of patients under careful mouth prophylaxis and that of those under indifferent management, that the bacterial influence in the production of stomatitic complications weighs more than any other factor except the accumulation of detritus which provides for the nourishment of a rich saprophytic flora in ill-kept mouths.

Stomatitis may occur in small groups of patients, apparently due to a common infection epidemic at the time rather than to the technic of treatment. A striking example of this was noted by one of us (J. H. S.) at the Mayo Clinic where in November 1919 an epidemic of tonsillitis *was associated with a wave of severe stomatitis, in spite of the usual precautions, in those* under mercurial treatment.

The oral hygiene appropriate to the general treatment of syphilis has been outlined in Fig. 175, and with its use the stomatitic manifestations, primarily of local origin as with bismuth and mercury, should become comparative rarities. A number of differential points, however, deserve emphasis. A heavy metal stomatitis and gingivitis is the product of the deposit of sulphide of the heavy metal about the capillaries of the mucosa. Edema, bleeding, lividity of the tissues and discoloration by the deposit, most marked in the case of bismuth, are features of all cases. The patchy, irregularly distributed pigmentation of the mucosa under bismuth treatment is relatively rare in moderate dosage and American authors have been inclined from their experience to

minimize bismuth stomatitis especially as rarely constituting a serious difficulty in ordinary dosage. On the other hand, with mercury stomatitis (Fig 191) is so common an occurrence that it is even regarded by some as a guide to therapeutic saturation and almost a goal to be reached With this point of view we take issue, considering the renal index of irritation the only safe one to employ In a case of nearly fatal accidental mercurial poisoning the renal

Fig 190

MOUTH WARNINGS OF TROUBLE
With Associated Groups of Symptoms
(Numerically Arranged in an Average Order of Appearanc)

From Arsphenamin
1 Dry red mouth.
2. Chapping lips.
3. Bleeding from the gums (not "pink toothbrush")
4. Purpuric stippling of gums or mucosae or outright hemorrhages, breaking dow to form ulcerations.
5 Marked exaggeration of pyorrheic ymptoms, or appearance of "trench mouth.
6. Gangrenous points, especially t sites of pyorrhea pockets.
7 Warning symptoms of bone marrow injury—fall in leukocytes, rise in eosinophils, drop in platelets.
8. Malaise, pallor itching of the skin, purpura.
9 Agranulocytic angina with gangrene.
From Bismuth.
1 Fetor (foul breath) A important early sign.
2. Blue line t gingival margin (look behind upper incisors)
3. Bluish spots in gums or mucosa (bisulphide) especially near third molars, cheeks, and tonsillar pillars.
4. Aching discomfort on clenching the ja ("bit test")
5 Edema of gums and tongue (especially around third molars)
6. Beginning "trench mouth
7 Gangrenous points or exudate around pyorrhea pockets.
8. Massi gangrene (with agranulocytosis).
9 Local adenopathy
From Mercury
1 Aching discomfort on lenching the ja ("bite test")
2. Swelling of gum flap over third molar makes biting painful at that site.
3. Edema of tongue and gums (especially recognizable bout third molars, pyorrhea pockets, nd imprints of teeth in sides of tongue)
4 Local adenopathy (submaxillary)
5. Increased flow of sali
6. Bleeding of gums.
7 Erosions and exudat gums and tongue.
8. Localized gangrenous points. Does not produce agranulocytic picture in mouth and throat
9 Mercurial pallor cachexia, anorexia, arthritis.
From Iodides.
1 Metallic tast (unimportant)
2. Possible occasional exaggeration of existing stomatitis.
3 Bullous and purpuric lesions (extreme iodism)
4 Parotid edema (iodide mumps)
5 Laryngeal edema nd iodide laryngitis.

symptoms reached a high degree of severity while it was still possible to control the stomatitis by a careful prophylaxis. In the extreme grades of mercurial stomatitis, involvement of the tonsils, pillars, soft palate and pharynx may be so severe as to simulate a Vincent s infection In fact, it is important to realize that Vincent s infections may be stimulated or even precipitated by such minor mercurialization as 2 grains of hydrargyrum cum creta by mouth

Peters (1942) has commented on the lack of attention given to the associ

ation of bismuth stomatitis and albuminuria. He collected from the files of the Johns Hopkins Hospital 6 cases of bismuth nephrosis or albuminuria with severe ulcerative stomatitis and 7 with a similar but mild complication.

Arsenical stomatitis (Fig 192) as we have seen it differs quite sharply from heavy-metal stomatitis in the dry red, glistening appearance of the mucous surfaces as distinguished from the lividity and exudative characteristics of heavy-metal stomatitis. There is, moreover no pigmentation unless the patient coincidently is taking bismuth A grave sign in all stomatitic conditions is the appearance of necrosis and of submucosal hemorrhage This warns not only of the severity of the stomatitis as such but of the development of agranulocytosis under arsphenamine or bismuth therapy or the onset of aplastic anemia. So important are these considerations that the appearance of a well-marked stomatitis of any type calls for a complete blood count with a study of the blood smear for the hematological signs of damage to the hematopoetic mechanism (Fig. 194) One should not wait until itching and eruption or purpuric hemorrhage appears. Stomatitis associated with pharyngitis and tra

Fig. 191 —Beginning mercurial stomatitis developing at the base of lower central incisor Note the early warning of the submental adenopathy The patient as taking inunctions

cheitis is an accompaniment and sometimes a warning of the onset of exfoliative dermatitis and its appearance is therefore a signal for the discontinuance of the arsphenamine until the situation can be evaluated. In general, it is a warning of a serious grade of idiosyncrasy to the arsenicals. The clean, dry hot, red, exfoliative characteristics of a stomatitis point to the arsenical factor although in occasional cases the bacterial flora of a gum pocket may start a secondary process resembling a heavy metal stomatitis and amenable to the same treatment.

Treatment of Stomatitis.—The intake of heavy metal or arsenical should at once be stopped and immediate investigation made to determine whether the stomatitis is associated with hematopoietic changes or not. If these blood studies are negative and the patient is taking mercury by inunction or is in a room with a patient who is taking inunctions, he should be placed in another room and if receiving inunctions, should be given two hot soap-and-water baths and a sweat (wet pack) If the heavy metal has been given intramuscularly in cumulative form there is nothing to do but fight it out, and every

effort should be made to keep up the patient's nutrition and spare his kidneys by rest in bed, a bland diet rich in carbohydrate in the case of heavy metal poisoning, fats and proteins if the hepatic complications of an arsenical injury appear. Alkalinization should be carried out, milk taken in abundance and sodium thiosulphate may be given in 0.5–1 Gm. doses intravenously every second day for 3 to 4 injections. Calcium gluconate intramuscularly 10 cc. of a 10 per cent solution may also be used every second or third day. The care of the mouth calls for the separation of the gums from the cheeks and the tongue from the teeth by thin strips of cotton soaked in boric acid solution or liquor antisepticus alkalinus, frequent changes of the cotton strips, a mouth wash every two hours of liquor antisepticus alkalinus containing ½ per cent zinc chloride or Dobell's solution, which has a comforting anesthetic effect, and the attention of a dentist to the gum pockets is very helpful, if available. In fact, in severe cases skilled dental aid is worth all the other measures combined and will control the most resistant tendency to relapse (*cf.* McCarthy and Dexter 1935).

Fig. 192.—Stomatitis produced by arsphenamine. There was no general reaction except dry angina.

In addition to the foregoing measures some assistance in dealing with the gangrenous lesions of agranulocytosis may be obtained by the use of ultraviolet light locally with the Kromayer lamp and dental applicators. In these cases, when due to the arsenicals, we are inclined to avoid the use of an arsenical even locally in the treatment of the stomatitic process. We have no personal experience with the use of vitamin C (Marin, 1942) and sodium hexametaphosphate (Felsher and Jones, 1941) as a dentifrice (15 per cent Na hexametaphosphate and 85 per cent talc) in the prevention of or treatment for bismuth stomatitis and pigmentation.

A severe attack of stomatitis as a local manifestation seems to predispose to relapses and mouth prophylaxis should be strictly adhered to while the heavy metal is very cautiously resumed. The caution about acid foods in the oral hygiene summary (Fig. 175) must be taken seriously. Sensitive persons have noticed effects from the eating of a single sour apple.

There is a distinct tendency on the part of the arsphenamines given intravenously to diminish the incidence of heavy metal stomatitis, probably through their effect on the Vincent flora. For this reason, if the patient is on heavy metal alone, neoarsphenamine may be resumed intravenously and a 10 per cent solution in glycerin also applied locally to the gums. A 10 per cent

hot sodium perborate solution is preferable to the packing of these Vincent mouths with powdered sodium perborate provided the solution is used hot and frequently under proper direction.

Iodide stomatitis in our experience is a very great rarity probably because it is usually cloaked by the ascribing of the cause to a heavy metal simultaneously administered. Of iodide pharyngitis and laryngitis we have seen only one case but the possibility should be kept in mind in giving treatment to laryngeal lesions, in which serious edema may be induced.

Gastro-intestinal Reactions.—The general preventive aspects of the control of the gastro-intestinal reactions have been presented in Fig. 176, page 380. Gastro-intestinal reactions to the arsenicals range from slight anorexia with or without nausea to intractable vomiting lasting for several days, and from a sequence of two or three rather voluminous stools on the night following an injection to a profuse watery diarrhea. In some cases the gastric symptoms particularly are associated by the patient with the disagreeable ether or garlic-like odor which he notes at the time he is receiving the injection particularly in the case of neoarsphenamine. The disagreeableness of this experience may start the train of gastric reactions in hypersensitive persons. There is also a close clinical relationship between the nitritoid vascular crisis and subsequent gastro-intestinal reactions, and the methods advised for the control of acute vascular reaction (p. 410) have decided value in reducing the tendency to gastro-intestinal reaction. We therefore regard the marked parosmia experienced during injection, the tendency to vascular reaction and the gastro-intestinal phenomena as part and parcel of the same reaction mechanism and are placed on our guard by their repeated recurrence accordingly. For the disagreeable odor and taste many patients experience great relief from allowing a peppermint, clove, or wintergreen wafer to dissolve on the tongue during the injection.

Vomiting on the table occasionally occurs in nitritoid crisis, but is usually the result of faulty preparation of the patient (see Fig. 193, p. 410). Nausea alone makes up the large proportion of late reactions during the ensuing twelve hours. About 60 per cent of patients receiving intensive drip arsenotherapy experience it, most severely on the first day. For this reason, where possible, it is advisable to give the drug in the morning so as not to disturb the patient's sleep. Most patients feel well enough by evening to protest if their meal is made too light. Those who vomit more than once should be given 2 glasses of warm water with a drachm (not a teaspoonful) of sodium bicarbonate. This is usually vomited again and the patient feels much relieved. If vomiting or nausea persists, cracked ice, chewed and swallowed (not melted in the mouth), an ice-bag to the pit of the stomach (sometimes a hot water bag is preferred), and carbonated water or ginger ale poured over cracked ice, will often relieve. Obstinate vomiting, lasting several days, sometimes responds to cold buttermilk and a good beer is occasionally specific. Arsenicals have a disagreeable trick at times of precipitating the gastric crises of tabes dorsalis and repeated severe vomiting should be carefully considered from this standpoint if the case is one of neurosyphilis. On very rare occasions gastric lavage may be employed or hypodermic sedatives necessary (codeine rather than morphine should be used). The onset of a jaundice is sometimes predictable from the recurrence of gastro-intestinal reactions or the unusual persistence of any given episode after treatment. Close attention should be paid to the sclerae and the urine.

early syphilis must be recalled If the fever lasts longer than twelve hours, the Herxheimer effect is practically excluded. The macular type of toxic eruption is faintly visible over the chest, abdomen and flanks, and fades within one or two days without desquamation. The papular type usually appears within forty-eight hours, is confined largely to the hands and arms and is often associated with the arthritis of the smaller joints that constitutes the so-called "arthritic reaction." The morbilliform or measly eruption is abundant and extensive the macules retiform and at times confluent over the trunk and extremities. This seldom appears before the third day and is strongly suggestive of measles except for the absence of Koplik's spots and coryza. At times there may be some dryness and redness of the mucous membranes and a cough which with edema of the lower lids and engorgement of the conjunctivae, may make the resemblance to measles marked enough to be deceptive. Some residual pigmentation or a slight furfuraceous desquamation may follow The scarlatiniform postarsphenamine erythema has a febrile prodrome usually shorter than the morbilliform type. A scarlet blush appears first on the face and extremities, spreading in varying degrees over the entire body There is sometimes considerable associated edema and the eyes may be swollen shut. There is however no exudation and the color remains bright instead of becoming livid or bronze as in true exfoliative dermatitis. The subsidence of the erythema about the third to fifth day is followed by a rather abundant, large, flaky desquamation and the palms and soles may peel in casts strongly suggestive of those seen after scarlet fever Mouth symptoms and angina are rare and we have never seen a suggestion of strawberry tongue This form of arsphenamine erythema is, in appearance, a close approach to exfoliative dermatitis and we personally believe that we have seen evidence of its passing over into exfoliative dermatitis after a lull or intermission (Fig. 197)

I fifty-two of Peters fifty-four patients there ere dermatologic manifestations. There was no correlation between the size of the dose and the occurrence of the syndrome. Fifty-two patients had two or more injections of the drugs before its appearance Over 70 per cent of the patients had general lymph node enlargement, enlarged palpable cervical nodes and tonsillar hypertrophy some had conjunctival suffusion. Hepatomegaly was noted in nine patients, and jaundice in seven. The syndrome lasted six days, excluding patients who became jaundiced, five days for the erythema and one day for the prodrome. There were no fatalities.

The immediate associated reactions, integral features of the syndrome, were mainly visceral and occurred in 24 per cent of this series. There were eight patient ith "hepatitis, four with hepatomegaly alone, two with nephritis and one each with splenomegaly alone and granulocytopenia. Delayed complications, caused by further treatment with the arsphenamine drugs, occurred in 43 per cent of thirty-six patients and consisted of dermatitis (all types), recurrent erythema of the ninth day nitritoid reactions, fever gastro-intestinal reactions and intolerance to the usual trivalent arsenicals. Of all patients receiving further arsenical preparations, 70 per cent had reactions. Of fifteen patients who had reactions to arsenical drugs prior to the occurrence of erythema of the ninth day 60 per cent developed serious sequelae to treatment after its occurrence.

In general, the blood smears showed shift to the left, and in severe cases there as mild leukopenia of the granulocytic series with relative monocytosis or lymphocytosis. Eosinophilia of 5 per cent or greater appeared in 44 per cent of patients. Of this group, 67.5 per cent had serious immediate manifestations or subsequent treatment complications, while of the patients with eosinophilia of 0 to 4 per cent, only 35 per cent had reactions. The likelihood of serious immediate or delayed complications increased with the degree of eosinophilia. Among patients receiving further arsenotherapy during or within two weeks of onset of the prodrome 77 per cent had serious complications, while of those who received treatment later than two weeks, only 23 per cent had complications and these were relatively mild. There ere two instances of infectious relapse of the syphilitic disease in this series. Peters concludes that the erythema of the ninth day syndrome predisposes to infectious relapse of the syphilitic infection when arsenotherapy is

hot sodium perborate solution is preferable to the packing of these Vincent mouths with powdered sodium perborate, provided the solution is used hot and frequently under proper direction.

Iodide stomatitis in our experience is very great rarity probably because it is usually cloaked by the ascribing of the cause to heavy metal simultaneously administered. Of iodide pharyngitis and laryngitis we have seen only one case but the possibility should be kept in mind in giving treatment to laryngeal lesions, in which serious edema may be induced.

Gastro-Intestinal Reactions.—The general preventive aspects of the control of the gastro-intestinal reactions have been presented in Fig 176, page 380 Gastro-intestinal reactions to the arsenicals range from slight anorexia with or without nausea to intractable vomiting lasting for several days, and from a sequence of two or three rather voluminous stools on the night following an injection to a profuse watery diarrhea. In some cases the gastric symptoms particularly are associated by the patient with the disagreeable ether or garlic like odor which he notes at the time he is receiving the injection, particularly in the case of neoarsphenamine. The disagreeableness of this experience may start the train of gastric reactions in hypersensitive persons. There is also a close clinical relationship between the nitritoid vascular crisis and subsequent gastro-intestinal reactions, and the methods advised for the control of acute vascular reaction (p. 410) have decided value in reducing the tendency to gastro-intestinal reaction. We therefore regard the marked parosmia experienced during injection, the tendency to vascular reaction and the gastro-intestinal phenomena as part and parcel of the same reaction mechanism and are placed on our guard by their repeated recurrence accordingly For the disagreeable odor and taste many patients experience great relief from allowing a peppermint clove, or wintergreen wafer to dissolve on the tongue during the injection.

Vomiting on the table occasionally occurs in nitritoid crisis, but is usually the result of faulty preparation of the patient (see Fig. 193, p. 410) Nausea alone makes up the large proportion of late reactions during the ensuing twelve hours. About 60 per cent of patients receiving intensive drip arsenotherapy experience it, most severely on the first day For this reason, where possible, it is advisable to give the drug in the morning so as not to disturb the patient's sleep. Most patients feel well enough by evening to protest if their meal is made too light. Those who vomit more than once should be given 2 glasses of warm water with a drachm (not a teaspoonful) of sodium bicarbonate. This is usually vomited again and the patient feels much relieved. If vomiting or nausea persists, cracked ice, chewed and swallowed (not melted in the mouth) an ice-bag to the pit of the stomach (sometimes a hot water bag is preferred) and carbonated water or ginger ale poured over cracked ice, will often relieve. Obstinate vomiting, lasting several days, sometimes responds to cold buttermilk and a good beer is occasionally specific. Arsenicals have a disagreeable trick at times of precipitating the gastric crises of tabes dorsalis and repeated severe vomiting should be carefully considered from this standpoint if the case is one of neurosyphilis. On very rare occasions gastric lavage may be employed or hypodermic sedatives necessary (codeine rather than morphine should be used) The onset of a jaundice is sometimes predictable from the recurrence of gastro-intestinal reactions or the unusual persistence of any given episode after treatment. Close attention should be paid to the sclerae and the urine.

Diarrheas may be said to begin arbitrarily with more than 3 stools following an intravenous injection. Postarsenical diarrhea rarely lasts more than a few hours and should not be too hastily controlled by constipating measures such as opiates, since this closes an important channel of elimination. The patient who has had 3 or 4 stools, however should not be given a cathartic unless the trouble persists, in which case 1 or 2 tablespoonfuls of castor oil may be used. Dietary error and improper preparation should be inquired into. Placing the patient for several days or a week on a very soft diet with much heavily buttered milk toast (the milk should be boiled) will sometimes do away permanently with irritability of the bowel under arsenical treatment.

Hematemesis and melena after the arsenicals occasionally occur in patients who have gastric or duodenal ulcer or without any demonstrable lesion of the gastro-intestinal tract. Painless vomiting of blood and the passing of tarry stools may begin a few hours after an arsenical injection. The patient should be put to bed with morphine and an ice-bag and immediate preparations made for transfusion, if necessary If an ulcer was previously demonstrated, a surgeon should be called at once The accident is fortunately very rare Melena may also occur quite without warning and sometimes in grave proportions following the rupture of a varix in the stomach secondary to an unsuspected or underestimated cirrhotic process in liver or spleen.

Abdominal Pain after Arsenical Injection.—In contradistinction to mercury which more frequently gives rise to abdominal pain, the arsenical gastro-intestinal reactions are generally painless and the occurrence of the symptom of pain suggests the possibility of gastric crisis or of an intercurrent cause such as infectious diarrhea. We have seen one case of perforative peritonitis following arsphenamine in a patient with syphilis and gastric ulcer in which immediate surgical intervention saved the situation. Symptomatic vomiting from abdominal complication must always be borne in mind and the reaction should not be considered casually Vomiting forms part of the syndrome of acute yellow atrophy after arsphenamine, but jaundice and hepatic enlargement usually precede it. The abdomen should always be carefully examined for signs of an acute abdominal process, the mere fact that the patient has had arsphenamine never being allowed to cloud the judgment or obscure the possibility of a surgical complication. This is especially true of patients with organic gastric lesions, such as ulcer

The nitritoid reaction has a marked gastro-intestinal phase (see p 391) but the onset is characteristically with a chill and sudden rise in temperature which is quite diagnostic. Vomiting also occurs in severe therapeutic shock and is part of the prodrome of a toxic erythema (ninth-day erythema, see p 419)

Gastro-intestinal Symptoms after the Heavy Metals.—In this respect mercury is the principal offender and the advent of bismuth has been a great relief to the often hard-pressed physician and patient. A certain amount of anorexia, often pronounced, is an almost invariable accompaniment of mercurial therapy but the combination of this form of treatment with the arsphenamines gives a much-needed tonic effect. Perhaps one patient in a hundred cannot take mercury by mouth without trouble, mercury with chalk being in our experience the best tolerated. Patients on inunction rarely have gastro-intestinal difficulties, but the mercurial intestinal symptoms, particularly diarrhea, are more often associated with insoluble mercurial salts. An ordinary looseness of the bowels can be controlled in heavy metal therapy by soft diet and boiled milk. Milk toast is particularly effective. The sudden diarrhea which follows at times the injection of either an insoluble or more often a soluble salt may be controlled by a drachm or two of paregoric after each stool for 2 or 3 doses, and rest in bed. A powder of bismuth subgallate with charcoal, 30 to 60 grains of each suspended in water or milk may be given

every four hours. Bloody diarrhea with tenesmus requires an ice-bag to the abdomen and rest in addition to the above measures and a dose of morphine hypodermically is sometimes necessary although its use should, as always, be a last and not a first resort. Careful inquiry after a heavy-metal diarrhea has nearly always pointed to an indiscretion in diet, especially the eating of a large amount of fresh fruit. No permanent intolerance usually results from these sporadic disturbances. Chronic diarrheas (persisting more than four days after the heavy metal is stopped) should not be too readily accepted as of drug origin and treated in merely palliative fashion. The emotional factors in diarrhea, especially with much mucus in the stools, must be considered and achlorhydria likewise, though it is difficult to deal with it while the patient is on heavy metal therapy. The stools should be microscopically examined for parasites and blood and the possibility of an infectious diarrhea or dysentery and of chronic ulcerative colitis considered. Proctoscopic examination sometimes discloses an ulcerative proctitis which may require local treatment and large, hot, saline irrigations. The colonic ulceration of severe heavy metal poisoning requires similar measures.

Constipation during heavy metal therapy is usually corrected by the coincident use of the arsenicals, but in the case of mercury taken by mouth may be obstinate and trying. The use of a mild alkaline laxative usually deals with these cases satisfactorily. A warning should be issued against the use of cathartics.

Mercurial colic which is reduplicated symptomatically in susceptible persons by iodide colic, though there seems to be no homologous reaction to bismuth in our experience, seems to be an actual idiosyncrasy to the drug and consists of abdominal pain or cramps, suggesting almost the pain of intussusception or acute obstruction without diarrhea and even with obstinate constipation. There may be diffuse abdominal rigidity and some distention but no localizing signs. Hot packs to the abdomen and turpentine stupes may give some relief but the recurrence of the trouble when the drug is resumed usually forces suspension of the form of treatment responsible. Rectal tenesmus, possibly localized expression of the same condition further down the tract, is occasionally solitary symptom after intramuscular mercurial injection but in our experience has not constituted serious obstacle to treatment.

The bismuth enteritis is a relatively rare complication in ordinary dosage and this makes bismuth the logical heavy-metal resort in patients with hypersusceptible gastro-intestinal tracts. Gastro-intestinal reactions occur however in one third of patients receiving sobisminol by mouth. Cramps, probably of iodide origin, occasionally occur after iodobismitol intramuscularly.

Vascular Reactions to the Arsenicals.—Vascular reactions are here distinguished from reactions in the hematopoietic system, which are separately considered as the next topic. The outstanding vascular reaction to antisyphilitic treatment is the nitritoid crisis. In the light of what we now know of the mechanism of this type of reaction, the outstanding cause must be considered a defect in technic—namely the too-rapid administration of intravenous medication. On the other hand, nitritoid crisis is known to occur after intramuscular injections of bismuth and bismuth-arsphenamine combinations and even after foreign proteins such as boiled milk. It rarely occurs, however after injections of mapharsen which is administered rapidly. The disturbance of the colloid balance may therefore be induced by a number of factors and is subject to a certain extent to a general preventive and treatment mechanism.

The warnings of vascular reaction are summarized in Fig. 193. Vascular reaction usually develops while the patient is "on the table" but it may be

Fig. 183.

WARNINGS, PREVENTION AND TREATMENT OF THE NITRITOID VASCULAR REACTION

and its Correlated Gastro-intestinal, Pruritic, Asthmatic, and Urticarial Reactions

Warnings:

1. For their recognition these require the exposure of patient neck and arm t the shoulder face in full view
2. In the first stag the earliest signs are as follows
   ( ) A deep breath or two.
   (*b*) Gulping t or three times in succession Watch the larynx.
   ( ) An xpression of anxiety or restlessness.
3. Th second stage begins with
   ( ) Suffusion of f ce and neck or red blotching Thi is late sign and will almost alw ys go on t full reaction, requiring adrenalin treatment.
   (*b*) Deep, apoplectic flush nd edema of the face and neck with or without urticaria nd flushing over the bod
   ( ) Choking.
   (*d*) Wheezing and stridor (asthma")
4. The third stage incl des
   ( ) Unconsciousness, pupil usuall dilated, eyes open.
   (*b*) Pulselessness and collapse (rare)
   (*c*) Slow recovery is the usual rule

Prevention

1. Slow injection of properly prepared drugs (see p 900) or use of mapharsen.
2. Attention t the empty stomach rule
3. In known susceptibles (including vagotonics") use seriatim the following
4. Atropine ¼ t grain hypodermically t enty t thirty minutes before injection.
5. Besredka immunization or ntianaphylaxis —give ¼ the full dose slowly intravenously follow by the remaining in forty minutes.
6. I syringe technics (10-cc volume) keep the tourniquet on for t or three minutes.
7. Use special solvent (glucose vitamin C)
8. Use (4) nd (5) combined.
9. For succeeding injections, if no contraindications, give preparation 50 mg ephedrine in capsule the night before and agai one hour before injection.
10. *Rout nely place such patients on calcium by mouth, 60 grain of the gluconat t to* three times daily
11. Give lcium gluconat intramuscularly 5 t 10 cc of 10 per cent sterile solution (ampule) one-half t one hour before injection
12. Change t nother drug only if thera se uncontrollable
13. A similar preventive regimen pplies t gastro-intestinal reactions, pruritus (as solitary symptom) urticaria and asthma after rsphenamine treatment
14. The tendency t vascular reaction nd it correlates may disappear spontaneously but repetition ith increasing severity in spit of preventiv measures is arning of seriou intolerance

Treatment

1. Stop the injection If recognized in the first stage keep needle i vei five minutes, try resuming injection very slowl If not or symptom recur ithdra nd proceed as in (3) nd (4)
2. Epinephrine solution 1 1000, 10 minims hypoderm lly ll massaged In severe reactions additional 5 t 10 minims ntravenousl if heart intact.
3. Reassure the patient.
4. Severel reacti ng patient require bed, alkali zat on, ttention t gastro-intest nal symptom

STOP NITRITOIDS AT THE START

delayed ten minutes or more and o ertake him on his way out of the office or treatment room in which case it has an unforgettable effect on anyone who

happens to witness it. In the delayed reactions following bismuth and bismuth arsphenamine sulphonate intramuscularly more than half an hour may elapse before the crisis develops and the symptoms are correspondingly more protracted alarming and, inasmuch as they usually take place on a street car or in a corner drug store disturbing to the equanimity of the patient and the reputation of the physician. The absent minded operator who does not watch his patient during the injection abruptly comes to a realization of the situation after the stage indicated in 2, Fig 193, which is the proper time to recognize a nitritoid crisis, is passed. In occasional cases the reaction may be fulminating in rapidity From the subjective standpoint the experience is a terrifying one for the patient, accompanied by a sense of suffocation and impending death which makes him very loath indeed to repeat the experience. The consequences are rarely serious if the injection be stopped on the first warning sign, but if the reaction is fully developed before it is observed by the operator it may be so serious as conceivably to cause death in weakened individuals with serious organic lesions. We have never however seen or encountered a record of death from true nitritoid crisis. The reaction, with its attendant gastrointestinal sequelae may cause miscarriage in pregnant women, as in the case recently reported by Halloran.

Prevention and Treatment of Nitritoid Reactions.—This is summarized completely in Fig. 193. An occasionally used preventive is the addition of 5 minims of 1 1000 epinephrine solution to each 100 cc. of injected solution (especially "606") but Lees found the combined atropine-antianaphylaxis preferable. Dissolving the arsenical in a vitamin C containing solvent (methyl glucamine ascorbate) may at times prevent the reaction

The relation between the severe gastro-intestinal reaction as species of sequela of the nitritoid crisis was recognized by Beeman, who pointed out the applicability of the same methods of treatment to both conditions. By combinations of antianaphylaxis and atropine alone without ny of the later added methods it was possible to carry number of patients who had developed marked reactivity which ould have been sufficient to force discontinuance of treatment, through their normal schedules.

Differential Diagnosis.—The nitritoid crisis must sometimes be rapidly differentiated mentally in the treatment room from conditions which may resemble it, including colloidoclastic shock (arsphenamine idiosyncrasy and bismuth intravenously) arsphenamine collapse cardiovascular collapse convulsive seizures (epileptic, eclamptic, hysterical) and manifestations of fear anxiety embarrassment, and minor hysteria. Colloidoclastic shock associated with acid arsphenamine administration and so-called "arsphenamine collapse" differs sharply from the nitritoid crisis as it develops, in that in shock the patient is pale, pulseless and collapsed, while in the typical nitritoid he is flushed, hyperactive, coughing, choking and with a bounding pulse that may later momentarily collapse. The complaint of pain in the back is rarely heard in nitritoid crisis and frequently in shock or collapse. Cardiovascular collapse produces a greenish pallor or cyanosis with dizziness, sweating low pulse and feeble heart sounds in marked collapselike contrast to the florid redness, coughing, wheezing and agitation of the typical nitritoid. The true epileptic convulsion is of course easy to recognize but petit mal may be more difficult, though it usually lacks the flush and vascular reactivity the patient simply muttering or mumbling, passing into unconsciousness with some ticlike movement, and presently regaining consciousness without treatment. An eclamptic

seizure is a tonic convulsion without striking vascular manifestations, the clenching of the jaw and convulsive rigidity being very striking Major hysteria is momentarily perplexing but the rigidity the catatonic state and particularly the symptom of holding the thumb rigidly across the palm, makes differentiation usually possible. Any hypodermic medication usually brings about an immediate recovery The flush and restlessness of simple agitation and minor hysteria become easily recognizable on knowing the mental and nervous state of the patient, though one or two experiences may be necessary to a definitive diagnosis. A search should always be made for definite stigmas of hysteria in patients showing reactions of this type Naborro believes the nitritoid reaction markedly influenced by psychic disturbances, although its rarity after mapharsen tends to lay the blame for nitritoid reaction on the drug

Other Vascular Reactions.—Mercury practically never produces clinically recognizable cardiovascular reactions as ordinarily employed in treatment. Bismuth we have seen given before cardiac collapse which may of course,have been *post hoc*. Attacks of paroxysmal tachycardia and occasionally bradycardia may be precipitated by the arsenicals in patients who have been subject to them. The effect of this group of drugs on the heart circulation is well illustrated by its tendency to bring on angina pectoris in patients with impaired coronary circulation, a consideration that must not be lost sight of in therapeutic tests. Management of such cases with reference to arsenical treatment is discussed in detail in Chapter XIX. The localized injury to the capillaries of the brain which forms the basis of serous apoplexy or hemorrhagic encephalopathy is described on pages 244 434

Cardiac death after arsenicals without any technical fault or idiosyncrasy can nearly always be traced to preexisting cardiac disease, usually syphilitic in character and especially involving the coronary vessels. This, with the effect of the therapeutic shock (Herxheimer) on aneurysm with resultant rupture and death is also fully discussed in Chapter XIX Complications of this kind can only be forestalled by careful study of the patient before treatment is begun and by great caution in the use of the arsenicals and practical exclusion of arsphenamine (606) in serious late cardiovascular lesions

Purpura and extensive capillary hemorrhage after an injection of an arsphenamine is a sign of the gravest import, and should be a warning never to repeat this form of treatment. Such a reaction is part of the picture of hematopoietic injury considered on page 413 The effect of arsphenamine on blood pressure discussed on page 244 has lost clinical interest, but the blood pressure of the pregnant woman should be taken before each intravenous injection as a means to detecting the onset of the intoxications of pregnancy

Acute cardiac accidents on the table should be treated with 0.5 to 1 cc. adrenalin solution 1 to 1000 subcutaneously or intravenously or if collapse is complete and no heart rate detectable with the stethoscope, by the intracardiac route Two to 5 cc. are injected into the ventricle in the fifth interspace about 2 cm. to the left of the sternal border Aspirate first, to be sure the ventricle has been entered A wait of two or three minutes after the intravenous injection of adrenalin is permissible, however inasmuch as these patients are sometimes not as dead as they seem and revive under artificial respiration in that length of time. A report by Bodon (see also Champlin) of revival after apparent death from syphilitic coronary arteritis, encourages the belief that this method may be used in acute accidents from this cause occurring following arsenical treatment

Reactions of the Hematopoietic System.—Current conceptions as to the rarity of this group of reactions would probably require modification if periodic blood examinations were made of patients showing malaise pallor pruritus and purpuric manifestations under arsphenamine treatment. Aplastic anemia causes 5 per cent of postarsenical deaths. It seems very probable that some degree of bone marrow injury comparable perhaps in frequency to hepatic injury from the arsenicals could be detected in this way Duke pointed out (Bronfin and Singerman) that the same group of fundamental injuries is capable of expressing itself in one patient by progressive anemia, weakness and prostration with a slow fatal outcome in a second with agranulocytosis and *subsequently infection, notably angina* when there is failure of regeneration of leukocytes and in still a third group in purpura with hemorrhage *when there occurs a considerable diminution in the blood platelets.* Some diminution with subsequent increase, according to Jui-Wu Mu follows the ordinary administration of neoarsphenamine, especially if there is fever

Fig 194

WARNINGS OF INJURY TO THE HEMATOPOIETIC SYSTEM
(Aplastic Anemia, Purpura, Agranulocytosis)

1 A history of hemophilia, anemia, hemorrhages, etc.
2. Evidence of general reactivity especially repeated severe nitritoids and gastro-intestinal reactions.
3. Pallor weakness.
4 Purpuric spots on gums, mucosae, skin of abdomen, wrists, ankles. Numerous *suggillations or unexplained "bruises.*
5. Bleeding gums. Mucosal hemorrhages.
6. Subconjunctival hemorrhage.
7 Epistaxis.
8. Hematemesis.
9 Black stools.
10. Stomatitis with *fetor*
11. Gangrene in the mouth or throat.
12. The blood count Drop in reds, normal or low color index, leukopenia, drop in granulocytes, rise (relative) in lymphocytes, drop in platelets, drop in reticulocytes, absence of immature forms normal to an anemic blood picture (Bronfin and Singerman).

The warnings of injury to the hematopoietic system are summarized in Fig. 194, and in the preceding résumés of preventive procedure emphasis has been placed on the steps necessary to detect them. Periodic blood counts of all patients who do not do well under treatment would in all probability be the most effective preventive device. Moore and Keidel and Moore and Foley extended the search for warning blood changes to the necessary prophylaxis of other forms of reaction, particularly dermatitis, pointing out that the changes found differed only in degree rather than in kind from those which marked the fatally reacting aplastic case. Semenza has also stressed the prophylactic value of periodic blood counts. Sternal puncture may be of value in certain cases not only to determine the fact of depression of bone marrow function but also for differential diagnostic purposes. Determination of the icterus index or Van den Bergh reaction may be of value in early detection of potential hematopoietic damage.

The onset of the aplastic process which results in one or other of the three groups of symptoms classified by Duke may begin within from twelve to

forty-eight hours after the injection It may follow the initial dose or any subsequent dose. Slowly progressive weakness and pallor may precede the hemorrhagic manifestations or the development of stomatitis by one or two weeks. In some cases, nitritoid reactions of increasing severity seemed to form a prodrome. Sometimes there appear a few purpuric spots on the lower extremities or abdomen a day or two after the injection preceding the fatal one

The clinical course is usually rapid, nonremittent and lasts rarely more than two or three weeks, although the so-called "primary or idiopathic types of aplastic anemia," according to Schneider have an average duration of six months. The tendency to early hemorrhagic manifestations is quite characteristic. Slight epistaxis slight bleeding from the gums, or an insignificant conjunctival hemorrhage may be the first symptom to alarm the patient sufficiently to bring it to the attention of the physician We have thought that easy bruising of the skin and the appearance of large black and blue spots, different from the small purpuric hemorrhages seen on the extremities and minimized by the patient on the ground that he always "bruises easily may have prodromal significance. As the disease progresses, bleeding from the mucous membranes becomes a prominent symptom. Fever is a common accompaniment, dependent in part on the proportion that the agranulocytic mouth symptoms and pulmonary complications bear to the picture as a whole Abdominal pain without hepatic or splenic enlargement is said by Bronfin and Singerman to accompany the cases with hematemesis and melena. The purpuric spots appear and fade in groups over the upper extremities and chest and there may be marked traumatic suggillations over the elbows and sacrum and erosive changes where heavy bleeding takes place into the mucous membranes. The prognosis is grave from the outset, but in our experience, patients who survive the fifth day have at least a fighting chance for life, though the term is a misnomer in view of the ineffectiveness of practically all therapeutic procedure In the more prolonged cases the great thing to be feared is intercurrent infection which closed the picture in one of our particularly hopeful experiences after some weeks of steady favorable progress under antianemic measures. Stephens noted beginning bone-marrow regeneration in one of his two cases.

The purpuric type of hematopoetic reaction may give rise to a very confusing picture simulating hemorrhagic encephalopathy as in the case reported by Lasersohn in which fatal hemorrhages took place into the brain and spinal canal as well as the mucosae skin, and viscera. In fact the terminal picture in a purpuric aplastic case may be that of cerebral hemorrhage rather than death from infection

The treatment of the hematopoietic group of complications consists first in immediate and probably absolute discontinuance of an arsenical when even traces of purpura have appeared in the patient. Mapharsen may at the hands of the expert be cautiously used as a substitute in exceptional cases. We do not, however favor this procedure. Sodium thiosulphate has been advised but should certainly not be continued beyond the three injections repeatedly mentioned Calcium in large doses by mouth and theoretically at least, intramuscularly would seem rational but one hesitates at the intramuscular administration particularly where there is a definite tendency to hemorrhage Fibrinogen thromboplastin coagulen, have been of no avail in the cases we have seen. Vitamins P K, and beef thrombin, while mentioned are as yet unevaluated or untried Scarborough (1940) and Gorrie (1940) secured what

they believed to be recoveries in hemorrhagic purpuras secondary to arsenic and bismuth but according to Quick (1942) the results were not sufficiently controlled to be trustworthy in view of the tendency to spontaneous recovery. Antivenin was used by Bronfin and Singerman in their cases without effect and Semenza found splenectomy of no avail in one case. In several of our patients with hemorrhagic purpura Koagamin (an oxalic acid containing extract of certain plants) intravenously was beneficial (Steinberg, Segal and Parris 1940). Blain and Campbell (1942) showed that a sterile aqueous solution of recrystallized oxalic acid intramuscularly was useful to control bleeding. The optimum dose was 20 mg. Every effort should be made to build up or stimulate the activity of the bone marrow by antianemic measures of the type employed by Minot, Castle and their co-workers, including the administration of large doses of liver extract (pernicious anemia fraction) without iron or liver extract administered parenterally. The dose should be large rather than small. Where agranulocytosis is marked, as in patients with severe stomatitis and angina pentose nucleotides may be tried. Jackson, Parker, Rinehart and Taylor benefited two cases of benzol poisoning as well as other cases of malignant leukopenia, by the use of this preparation (NNR). Burke also found this to be of value. We have used leucocytic cream (transfusions of blood from leucemic patients) with probably good effect. Burke thought such transfusions of decided benefit. In cases associated with marked blood loss from hemorrhage the Whipple fraction of liver with iron may be used. In addition, cod liver oil in large doses should be given or the anti-infection vitamins A and B in the form of halibut liver oil, a brewers' yeast extract or other B complex preparations and vitamin C. We have not tried vitamin P. Irradiation of the patient with the carbon arc or sun lamp (not necessarily short wave ultraviolet) and the sedulous exclusion of all sources of infection from visitors and so forth is imperative. The administration of hydrochloric acid and of extracts of gastric mucosa or whole stomach must be governed by the indications under the guidance of an expert hematologist. All things taken together, we have felt that the small transfusion (250 cc.) frequently repeated, has probably as high a sustaining value as any single measure. Occasionally unfavorable reactions seem to ensue, but are probably merely part of the course of the complication.

The steady decline of the foredoomed case only too often illustrates our fundamental helplessness in the face of an inevitability dependent on biological exhaustion or ruinous intoxication of an essential structure like the bone marrow.

The lack thus far of evidence of unfavorable effect from simultaneous use of two hematopoietotropic drugs has been mentioned but deserves further study. The injury involved seems highly specific for the individual drug.

Syphilis complicated by pernicious anemia furnishes a special problem in treatment and the prevention of reactions which was studied by several authors, including Fouts and Stokes. The tremendous modification of the prognosis and treatment of pernicious anemia since this study makes a reinvestigation of the whole question desirable but one or two points still deserve emphasis. Bismuth is preferable, of course, to mercury as a heavy metal in such cases and neoarsphenamine preferable to arsphenamine (606). It would seem that bismuth arsphenamine sulphonate could have a field of usefulness here. Transfusion should be a preliminary to arsenical treatment when the hemoglobin is below 50 per cent but under present practice liver therapy will, of course, be used coincidently or antecedently. Reactions to arsenical injections must be carefully avoided since they may produce an alarming drop in hemoglobin. No satisfactory rule for determining which case would improve on treatment for syphilis and which case would not, can be arrived at, about half the cases improving under the older regimen. Frequently repeated blood counts are necessary as indices of progress.

Hepatic Complications.—The causal mechanism is considered on page 248 and the differential diagnosis is discussed in Chapter XVIII because of its close association with the symptomatology of syphilis of the liver

In Fig 195 is presented a series of warnings of hepatic complications which, though more or less irrespective of the type applies particularly to intercurrent catarrhal or so-called "postarsphenamine jaundice" and the acute yellow atrophies. The rôle played by the liver in the economy of the patient with syphilis is so large that with the improvement of liver functional tests it would seem justifiable to employ them in an anticipatory way to recognize at least subthreshold bilirubinemia. All patients who are not doing well under treatment should be scrutinized for signs of hepatic difficulty including palpation of the liver enlargement of which may precede the onset of definite jaundice.

Treatment decisions must rest on a careful differentiation (see p. 248) of the possibilities involved. It is usually advisable to shift, even in an apparently

Fig 195

WARNINGS OF HEPATIC COMPLICATIONS

1 Evidence of general reactivity: severe nitritoids, gastric disturbances, patient not doing well.
2. Anorexia.
3 Abdominal discomfort or actual distress, rarely sharply localized.
4 Light stools (not necessarily clay colored)
5 Dark urine.
6 Bilirubinemia as indicated by icterus index.
7 Stiff joints (especially shoulders and back.)
8 Yellow sclerae.
9 Liver may or may not be palpable or enlarged at the start, may shrink in size (atrophy)
10. Fever
11 Deepening jaundice
12. Abdominal pain, liver tenderness, confusion, delirium or stupor prostration (acute yellow atrophy) May appear early usually late.

SOME LIVER INJURY PROBABLY ACCOMPANIES ALL TREATMENT WITH ARSENICALS, AND MAY BE SERIOUS

syphilitic icterus, from the arsenicals to bismuth and to push it with reasonable vigor for a period of weeks before returning to the arsenicals when the trouble has subsided The tendency for bismuth preparations to cause hepatic injury and jaundice should not be forgotten (Nomland, Skolnik and McLellan (1938) Gott and Doyle (1939) Lane (1939) Wolman (1940) Kulchar and Reynolds (1942)) O'Leary and Rowntree emphasized the seriousness of these cases from the standpoint of future embarrassment in treatment and the possibility of later hepatic complications. In early cases in which it is imperative to continue arsenical treatment this may be done provided the picture conforms to the catarrhal type, but neoarsphenamine or mapharsen should be substituted for arsphenamine and repeated blood counts taken to be sure that no arsenical injury to the hematopoietic structures is taking place General detoxification measures can also be carried on in these patients hand in hand with the treatment of the syphilitic infection. A large body of experimental and clinical evidence has been accumulating to show that the liver may be spared by a diet high in protein. Carbohydrate is beneficial though to a lesser degree while

a fat diet proves deleterious (cf Craven (1031) Schifrin (1032) Beerman (1934) Goldschmidt, Vars and Ravdin (1939) Miller and Whipple (1940) Messinger and Hawkins (1940) Johnson, Ravdin, Vars and Zintel (1940) Mann (1041) Ravdin, Thorogood Riegel Peters and Rhoads (1943)) The greatest degree of symptomatic relief, particularly in the catarrhal type of case, comes from duodenal lavage as used by Wilhelm from the Mayo Clinic service following the technic of Lyon This procedure is so useful and so entirely harmless that it is here quoted:

> The tip of the tube is placed on the tongue, close to its base and the patient is told to swallow During the act of swallowing, the tube is started gently down the esophagus and is passed until level of about 40 cm mid y between the first and second markings, is reached. At this level the stomach is washed with sterile water until the return is clear The patient is then instructed to lie on his right side, extending his right leg and acutely flexing his left knee and hip He is told to pass the tube t the rate of 1 inch every five minutes until the third mark (75 cm.) is reached. W know that the tube is in the duodenum by change in reaction of the aspirated fluid from acid to alkaline by the character of the duodenal juice, which is usually a pearly viscid fluid, in which floccules are suspended sometimes by the presence of bile; by slight tug when the tube is pulled gently and by seeing the tip beyond the pylorus at fluoroscopic examination. (This is not usually necessary.) The tube is removed by withdrawing it gently until the tip reaches the nasopharynx. The patient is then told t swallow and the tip is easily recovered
>
> When the tube is in the duodenum, the latter is washed first with water at 40 C. and about 100 cc. of saturated solution of magnesium sulphate is washed back and forth in syringe with capacity of 100 cc. for about ten minutes. The duodenal contents are then allowed to siphon out. This process is repeated three or four times at intervals of thirty minutes. The tube is then ithdrawn, the stomach being washed again at this time, and the tubing being repeated every other day From one to eight tubings may be necessary nd the striking good effect is often recognized following the first or second lavage

Hanger and Gutman (1940) confirmed the value of dealing with post arsphenamine dermatitis as an obstructive jaundice in their employment of serum phosphatase determinations and cephalin flocculation tests to differentiate the obstructive from the parenchymal injury cases. They base their recommendations on drainage of the biliary tract and the use of choleretics such as bile salt preparations and cholic acid derivatives in treatment.

In addition to these measures or in cases where they are inapplicable, glucose intravenously may be employed, as suggested under general detoxifying measures. Sodium thiosulphate is not particularly useful either in our experience or that of Colonel Harrison Appel and Jankelson (1935) found sodium dehydrocholate useful as a solvent for neoarsphenamine to protect the liver by improving arsenic elimination so that patients could continue therapy even in the presence of jaundice. During the jaundice a diet of milk, eggnog, toast and fresh fruit has seemed helpful, and an occasional mild course of calomel and sodium phosphate, with oxgall tablets as suggested by Eppinger to diminish the viscosity of the bile. Simici and Popesco found that insulin favorably affects the hyperbilirubinemia of "postarsphenamine jaundice and shortens the course of the complication. It also combats the tendency to emaciation.

In view of the apparent usefulness of liver extract in certain arsphenamine complications, including dermatitis (Spiethoff MacKee and Astrachan) its trial in toxic hepatitis seems fully justified, but we have no personal experience with it.

Acute yellow atrophy like aplastic anemia, has a hopelessness and an even greater unpredictability which makes it the rival of arsphenamine dermatitis

as a mortality factor on large services. The symptomatology is marked by an onset that may immediately follow an arsphenamine injection or be delayed for weeks or even months. Out of a clear sky the patient rapidly becomes jaundiced with associated intense abdominal pain, tenderness over the liver and great prostration. Drowsiness, stupor and coma supervene on delirium; fever is frequently present, the urine contains bile, tyrosin, leucin, and the liver at first large begins to decrease in size as coma sets in. Death may occur in from three days to a week or more and the conventional treatment by alkalis, sodium thiosulphate, fluids, glucose intravenously is rarely of any avail. As in acute arsphenamine poisoning, there may be associated both dermatitis and peripheral neuritis, and likewise aplastic anemic manifestations

Fig 194

WARNINGS OF TROUBLE WITH OR FROM THE SKIN

General.
1 A history of irritable skin—trouble with soaps, cosmetics, sunburn.
2. The seborrheic state—dandruff (marked) oily skin, acne (or its scars), presternal and interscapular patches of scaling dermatitis.
3. The allergic state—a history or symptoms of asthma, hay fever, repeated attacks of hives.
4 The "vagotonic" or "high-strung" nervous state—red face and neck, blue hands and feet, "inward nervousness."
5 A history of eczema, personal or familial
6. A history of known specific drug sensitivities. Local reactions to iodine, etc.
7 A high carbohydrate diet or alcoholism.
8. A heavy load of focal infections.
9 An acute infection or exposure to cold (Harrison)
10. Marked repeated vascular and gastro-intestinal reactions, evidence of poor tolerance in general, ... nervous irritability

Special.
1 Itching on the day following injection. Never disregard it, especially with (2)
2. Stippled red rash, flexures, face and neck. Transient at outset. Inquire for it
3. Edema of eyelids.
4. *Chill and fever following arsphenamine (eighth-day erythema)* with florid rash fourth to eighth day
5. Patches of dermatitis or "eczema," recent or long-standing. Examine extremities, groins, hands especially. May also be dermatophytic or examples of "fixed arsphenamine exanthem
6 Large subcutaneous suggillation and nontraumatic black and blue spot
7 Purpura, especially noticeable about flexures, wrist and ankles, abdomen, mucosae
8 Pallor
9 Jaundice.
10 Stomatitis (arsenical type)
11 Blood count. Rise in eosinophils, drop in leukocytes, erythrocytes, platelets, immature red cells in smears.

with hemorrhages. Mistaken operative interference in intercurrent catarrhal jaundice has been known to be followed by a fatal picture suggesting acute yellow atrophy. It is, furthermore, essential to differentiate acute yellow atrophy of arsenical intoxication from that of syphilis, the latter being fortunately extremely rare. The symptomatology is essentially identical. Positive serological reactions and no history of treatment usually accompany the syphilitic form.

The Cutaneous Reactions.—While the skin, because of its visibility and extent, displays a disconcertingly large variety of reactions to treatment for syphilis, their occurrence is fortunately a comparative rarity (one in one thousand injections on a hospital service) and only two of them, arsenical

toxic erythema and arsenical exfoliative dermatitis, are of great practical importance. The types of cutaneous reaction to arsphenamine, bismuth, mercury and the iodides have been considered respectively on pages 245, 200, 217 and 220. The causal mechanism underlying the dermatitic types of cutaneous reactions was discussed on page 254. It remains, therefore, to consider the clinical symptomatology and treatment.

General detoxification measures may be considered as called for in all cases, regardless of type. Most inflammatory responses in the skin have two distinct groups of causes, the predisposing and the exciting, and failure to give adequate attention to the predisposing element in one's concern with the exciting factor usually results in prolongation of the course and relapse. This is especially true of the various forms of dermatitis attributable to treatment. In Fig. 190 are arranged the warnings of trouble with or from the skin so that the general warnings are of the nature of predisposing causes or background for the symptomatic or special picture of the case. Growing knowledge of the field is tending to emphasize more and more the importance of cutaneous manifestations as expressions of a systemic rather than a local process with underlying injuries to the bone marrow, liver and vascular system as well as the excretory mechanism as the principal elements in the perverted metabolism leading to reaction.

Arsenical pruritus and urticaria may be treated by the use of adrenalin or ephedrine as previously described. A shift of drugs and sometimes no therapeutic measure whatever may bring about a disappearance of the symptoms. Pruritus should always be carefully investigated for its possible connection with dermatitis exfoliativa on the one hand, in which it may terminate, and aplastic anemia and liver injury, of which it may be a symptom. The use of calcium and glucose as a buffer may be helpful.

The Erythema Multiforme Group—Ninth-Day Erythema.—These are the acute cutaneous reactions identical with those to which the name "ninth-day fever" or "ninth-day erythema" is applied.

Since the original descriptions (Milian (1917), Stokes (1940)) this phenomenon has been studied particularly by Peters (1941), Drummond (1941), Cathcart and Thomas (1939); Epstein and Levin (1939), Goldman and Clarke (1939); Robinson (1938); Goldman and Werner (1936); Gordon (1936).

These reactions are usually associated with a prodromal chill and fever which according to the accepted European descriptions usually appear on the seventh to the twelfth day after the institution of arsenical, rarely bismuth treatment, thus presenting something apparently suggestive of an incubation period. The patients receiving massive dose arsenotherapy who develop secondary fever (64 per cent) and (about 46 per cent) an accompanying erythematous eruption are thought to be exhibiting manifestations of ninth-day erythema. The prodrome usually appearing within twelve to forty-eight hours after an injection (usually the second or third in American practice) consists of headache, backache, stiffness and malaise, sometimes with obstinate vomiting or diarrhea. A febrile reaction at this stage of treatment which lasts more than twenty-four hours after the drug has been administered will almost certainly terminate in a toxic eruption of some type, usually by the third or fourth day, the eruption taking a scarlatiniform, a morbilliform, a rubeoliform, a polymorphous or an urticarial aspect (Milian). The differentiation from a cutaneous Herxheimer effect in

early syphilis must be recalled. If the fever lasts longer than twelve hours the Herxheimer effect is practically excluded. The macular type of toxic eruption is faintly visible over the chest, abdomen and flanks, and fades within one or two days without desquamation. The papular type usually appears within forty-eight hours, is confined largely to the hands and arms and is often associated with the arthritis of the smaller joints that constitutes the so-called "arthritic reaction." The morbilliform or measly eruption is abundant and extensive, the macules retiform and at times confluent over the trunk and extremities. This seldom appears before the third day and is strongly suggestive of measles except for the absence of Koplik's spots and coryza. At times there may be some dryness and redness of the mucous membranes and a cough which, with edema of the lower lids and engorgement of the conjunctivae, may make the resemblance to measles marked enough to be deceptive. Some residual pigmentation or a slight furfuraceous desquamation may follow. The scarlatiniform postarsphenamine erythema has a febrile prodrome usually shorter than the morbilliform type. A scarlet blush appears first on the face and extremities, spreading in varying degrees over the entire body. There is sometimes considerable associated edema and the eyes may be swollen shut. There is, however, no exudation and the color remains bright instead of becoming livid or bronze as in true exfoliative dermatitis. The subsidence of the erythema about the third to fifth day is followed by a rather abundant, large, flaky desquamation, and the palms and soles may peel in casts strongly suggestive of those seen after scarlet fever. Mouth symptoms and angina are rare and we have never seen a suggestion of strawberry tongue. This form of arsphenamine erythema is, in appearance, a close approach to exfoliative dermatitis and we personally believe that we have seen evidence of its passing over into exfoliative dermatitis after a lull or intermission (Fig. 197).

1 fifty-t of Peters' fifty-four patients there ere dermatologic manifestations. There was no correlation between the size of the dose and the occurrence of the syndrome. Fifty-two patients had two or more injections of the drugs before its appearance. Over 70 per cent of the patients had general lymph node enlargement, enlarged palpable cervical nodes and tonsillar hypertrophy; some had conjunctival suffusion. Hepatomegaly was noted in nine patients, and jaundice in seven. The syndrome lasted six days, excluding patients who became jaundiced, five days for the erythema and one day for the prodrome. There were no fatalities.

The immediate associated reactions, integral features of the syndrome, were mainly visceral and occurred in 24 per cent of this series. There were eight patient ith "hepatitis," four with hepatomegaly alone, two with nephritis and one each with splenomegaly lone and granulocytopenia. Delayed complications, caused by further treatment th the arsphenamine drugs, occurred in 53 per cent of thirty-six patients and consisted of dermatitis (all types), recurrent erythema of the ninth day, nitritoid reactions, fever, gastro-intestinal reactions and intolerance to the usual trivalent arsenicals. Of all patients receiving further arsenical preparations, 70 per cent had reactions. Of fifteen patients who had reactions to arsenical drugs prior to the occurrence of erythema of the ninth day 60 per cent developed serious sequelae t treatment after its occurrence.

In general, the blood smears showed shift to the left, and in severe cases there as mild leukopenia of the granulocytic series with relative monocytosis or lymphocytosis. Eosinophilia of 5 per cent or greater appeared in 44 per cent of patients. Of this group, 87.5 per cent had serious immediate manifestations or subsequent treatment complications, while of the patients with eosinophilia of 0 t 4 per cent, only 35 per cent had reactions. The likelihood of serious immediate or delayed complications increased with the degree of eosinophilia. Among patients receiving further arsenotherapy during or within two weeks of onset of the prodrome 77 per cent had serious complications, while of those who received treatment later than two weeks, only 29 per cent had complications and these were relatively mild. There ere t instances of infectious relapse of the syphilitic disease in this series. Peters concludes that the erythema of the ninth day syndrome predisposes to infectious relapse of the syphilitic infection when arsenotherapy is

ithheld too long. N other effect on the course of syphilis w noted. The further administration of arsenical drugs should be withheld for at least one month following recovery from the reaction and should then be resumed cautiously ith small doses.

Part of the practical importance of the toxic erythemas aside from the discomfort they cause the patient lies in the reaction of the physician to the situation Milian has insisted that treatment can be continued after these reactions and we have personally confirmed this observation. On the one hand the hesitation of the physician in view of his proper fear of exfoliative dermatitis, is natural and a considerable hesitation and circumspection in resum-

Fig 197

TRANSITION TO EXFOLIATIVE DERMATITIS FOLLOWING ARSPHENAMINE NINTH-DAY ERYTHEMA

Association with Intercurrent Infection and Local Irritation (Inunctions)
Woman aged forty years, widow boarding-house keeper

10/22/20 **Entered Clinic with Maculopapular Secondary Syphilid** History of exposure duration of infection not known. Serum Wassermann reaction + + +
Cough Since Childhood, of increasing severity during the last t years.
Pain in Chest, Hoarseness, Roentgenogram Shows Tuberculosis of the Left Upper Lobe Sputum negative A few coarse rales. Temperature normal. N loss of weight.
First Arsphenamine Injection 3 dg Vomited. Secondary syphilid disappearing
Second Arsphenamine Injection 3 dg four days later No reaction.
Four days later pharyngitis, tonsillitis, palpable cervical glands, hacking cough audible rhonchi, nose running, temperature 101 F
Papular dermatitis on arms and legs, face swollen. *Patient had not received any mercury*
Put to Bed in Hospital Given 500 cc. Fischer solution (hypertonic saline and sodium carbonate) by rectum Temperature fell to normal in t elve hours.
Dermatitis Disappeared in Five Days. Probable ninth-day erythema.
Third Arsphenamine Injection 1 dg Given 500 cc. Fischer solution by proctoclysis in the following twenty-four hours. N complications.
Fourth and Fifth Arsphenamine Injections one and two eeks later 2 and 3 dg.; Fischer solution as before N complications.
Sixth and Seventh Arsphenamine Injections *3 dg 4 dg Through an oversight Fischer solution was not given after the sixth and seventh injections*
Dermatitis reappeared three day after the seventh injection ithout accompanying febrile or infectious symptoms, *following an attempt to begin inunctions* on the order of an inexperienced physician.
Typical Early Exfoliative Reaction Followed, controlled in ten days by:
Colloid bath, twenty minutes four times day
Potas imperialis by mouth.
Fischer solution by rectum.
Lassar paste (without salicylic acid) pplied to the skin between baths.
Tonsils showed evidence of chronic infection t this time

ing arsphenamine treatment are quit pardonable. On the other hand as Gjessing points out, early cases may be needlessly deprived of the benefits of an arsenical therapy a matter which was perhaps more serious in the mercurial days than under the present bismuth regimen. A certain number of arsenical erythemas must be regarded as inevitable and the possible instrumentality of an infection factor considered. Gjessing believes they are vascular infection-intoxication syndromes like the exanthemata. Fortunately the reaction is self-terminating and in the large majority of cases a change to a different type of drug permits the continuance of treatment.

The management of the acute process must be largely ymptomatic.

Salicylates sometimes seem to afford great relief but at other times are in effective. Alkalinization is useful. Great care should be exercised to protect the patient from chilling or the acquiring of an infection which may result at once in a rapid generalization of the dermatitis. Striking responses should not be too promptly attributed to the form of treatment employed.

The interrelation of ninth-day erythema with other forms of dermatitis occurring in the course of treatment which may assume something approach ing an exfoliative cast, is illustrated in Fig 197 Recurrences of ninth-day erythema with subsequent arsphenamine treatment but with diminishing severity have been recorded by Milian.

Treatment of Other Minor C taneous Complications.—The fixed exanthem, described by Naegeli in 1917 which takes the form of one or more urticarial plaques, reappearing at the same sit within few minutes to an hour or tw after injection and subsiding with residual pigmentation in the affected area or becoming lichenoid and sometimes eczematous, has been discussed in the American literature by Goldberger by Hazen, and by Chargin and Leifer (1940) and Mendelsohn (1940) is of unknow cause nd there is no known method of treatment. A spot of deepening pigmentation without preceding urticarial manifestations may develop When treat ment is discontinued the residue fades slowly Fixed eruptions produced by the arsenicals nd heavy metals are apparently identical in every respect with eruptions of similar type produced by other drugs.

Chargin and Leifer reported 60 in syphilitic patients 79 per cent occurring in the Negro, 19 per cent in the hite and 2 per cent in the yellow race.

Lesions ere most common on the face and were also observed over the entire body except on the scalp, palms and soles. The mucous membrane of the mouth was involved in t cases. Successful full-thickness autotransplants in three patients failed t react when the drug was readministered.

In spite of continued arsenotherapy no case of exfoliative dermatitis or any other type of arsenical dermatitis was observed in a patient having fixed eruptions. Since all trivalent arsenicals do not produce the fixed reactions with equal frequency it is possible t continue therapy uneventfully by change of arsenical. The various forms of herpes associated with arsphenamine and bismuth respond, following the discontinuance of the drug, t unfiltered roentgen-ray ultra violet exposure utohemotherapy and drying treatment ith simple calamine lotion. Ointments should be voided. Severe and extensive herpes zoster in these cases produces scarring characteristic of the condition. In one patient under treatment one of us (J H. S.) saw severe herpes zoster of the neck and right arm develop ith slight febrile reaction several days after an arsphenamine injection. T his astonishment, exactly fourteen days later this patient roommate developed chickenpox, a well-known association hich leads one to suspect that the herpetic omplication is an infectious incident as well as that the virus of the two conditions is identical.

Pigmentation and keratoses following the arsenicals cannot be materially affected by treat ment. When, ho ever the former occurs in association with dermatitic process it gradually fades. In severe cases of postarsphenamine dermatitis in brunettes it may be so deep as to suggest a mulatt tint. It is usually most abundant over the trunk but may involve the entire skin. A patient seen hen she had dermatitis and a mahogany-brown universal pigmentation, was rendered unrecognizable for us through recovery of her normal color hen seen six years later Argyria, of course is irremediable except as the local treatment described by Stillians and Laws can be pplied. Dohi has described postarsphenamine vitiligo or leukomelanoderma, ttributed to sympathetic nerve injury and Cannon and Karelitz have reported 3 cases of vitiligo following rsphenamine dermatitis.

The lichenoid or lichen planus-like arsphenamine eruptions respond as does lichen planus to unfiltered roentgen-ray irradiation, calcium and ultraviolet therapy and utohemotherapy

The pityriasis rosea-like exanthems and the flare-ups of dermatophytic processes observed under prolonged arsenical therapy and occasionall ith bismuth are believe exacerbations of mycotic eruptions and respond therapeutically t roentgen-ray irradiation, simple antipruritic lotions, weak sulphur ointments (1 t 2 per cent ith equal amounts of salicylic acid) and washes of 1 t 8000 potassium permanganate solution here they involve the flexures. A reduction in carbohydrat intake is essential here as in the exacerbations of seborrheic processes observed by Lee Harrison and Stokes. New types of arsenical cutaneous manifest tions have been recently reported which deserve mention vesicobullous dermatitis (Moir 1937); and reticular fibro-atrophoderma (Epstein, 1936) Benedek (1938) has collected group of cutaneous

disorders occasionally associated with arsenical and heavy-metal therapy (seborrheic dermatitis, pompholyx, pityriasis rosea and psoriasis vulgaris) under the title of "biotropic skin exanthems of known bacterial and hematogen endogenous origin" The various cutaneous and pigmentary disturbances from bismuth have been listed on page 200.

True Postarsenical Exfoliative Dermatitis—To this, the most serious of the cutaneous complications of treatment for syphilis, the term "late dermatitis" or "late exanthem" is often applied to distinguish it from the ninth-day erythema. Our observation would indicate that the individual who from the start shows a more marked cutaneous reactivity than the average, either by an outbreak of urticaria or ninth-day erythema is one likely to become the victim of true exfoliative dermatitis but this is by no means necessarily so As has been pointed out in the early part of this chapter the cutaneous explosion may be one of the unavoidable complications of even a properly conducted arsenical therapy and may appear early in the course of treatment,

Fig 198.— Fixed arsenical exanthem on the flexor surface of the forearm. This was the only lesion present. Originally urticarial, it recurred at first with each injection and finally became lichenified eczematous hyperpigmented plaque

though usually after the fifth to seventh injection. True exfoliative dermatitis, indistinguishable clinically from that produced by the arsenicals, may be produced by tryparsamide by mercury and by bismuth but is a comparative rarity Epstein (1937) believed that bismuth plays a major role in the production of dermatitis since he observed more cases in patients treated *with* the arsenical and heavy metal simultaneously This complication, it will be recalled, ranks second only to hemorrhagic encephalopathy as the most fatal of all unavoidable complications of a properly conducted arsphenamine therapy Its causal mechanism is considered on page 254

Prodromal Period and First Stage.—Postarsphenamine exfoliative dermatitis, dermatitis exfoliativa, or crustaceous dermatitis, tends in the majority of cases to follow a fairly definite course, with forewarnings constituting the first stage which, if recognized and treated may avert the attack. These prodromes with their general background are summarized in Fig 196 While one who is perfectly familiar with his ground may continue the treatment of

a patient under special precautions, after the appearance of one or another of these prodromes, the average physician invites trouble if he does so without advice. The second stage usually follows the repetition of the arsphenamine injection, which caused the prodrome, but may be delayed until after two or three injections.

Second Stage —Usually within twenty four hours after the injection which is to precipitate the severe attack, a general flush appears, most marked over the face and trunk with patches of dry or slightly oozing dermatitis, especially in the flexures and dependent portions of the body such as the feet and pretibial regions Itching is usually severe and the seriousness of the outlook may be to some extent gauged by the severity of this symptom by the degree of edema, and by the lividity or dusky bluish color of the involved skin. Figs 199 and 200 are typical of the severe attack. The general irritability of the

Fig 199 —Note the edema of the face early in the onset of serious arsphenamine dermatitis (Collection of Dr Joseph V Klauder)

patient is greatly increased and during the first three or four days it is almost impossible at times to secure his cooperation Chilling becomes very pronounced, due in part to the tremendous cooling effect of the cutaneous vasodilation. The patient's teeth may chatter in a room too warm for ordinary comfort. So continuous is this symptom that it may be difficult to recognize the really severe chills which often accompany the appearance or extension of the process and of coincident intercurrent infection which is often of the respiratory type. Fever may or may not be present (it appeared in two thirds of our cases, half just before and half during the dermatitis) but in the most severe cases usually reaching a peak of 102° to 105° F following a chill and then subsiding to the diurnal rise and fall of a septic temperature (see Fig 201)

It is at this stage as Moore and Keidel point out, that the blood picture is of value in detecting changes suggestive of early aplastic anemia and of marked irritation of the bone marrow

They found a striking increase in eosinophils, as high as 60 per cent in occasional cases, and in 14 of 16 observed patients there occurred an early leukopenia with decrease in polymorphonuclear neutrophils. Even an associated intercurrent infection, while producing a leukocytosis, was not sufficient to raise the proportion of neutrophils to the usual extent. Other cells of bone marrow origin appear in more severe cases, the large mononuclear transitional group even reaching the proportion of 30 per cent. Occasionally myelocytes and myeloblasts appear In extreme cases the bone marrow cells also disappear producing the picture of an aplastic anemia with extreme leukopenia and no signs of regeneration. These blood signs are all of some prognostic importance.

Third Stage —When the dermatitis becomes universal, the process settles down to a long course, seldom less than eight weeks and often as long as

Fig. 200.—Arsphenamine dermatitis. (Collection of Dr Joseph V Klauder)

twelve or more. The skin, at first deep red, edematous and oozing, becomes browner drier more leathery and scaling. The patient rapidly loses weight, and the skin, excoriated by scratching, hangs in folds. The hair thins, the nails usually are lost. Secondary inflammatory and infectious processes such as furuncles and mastitis develop Lymphadenopathy becomes general. The serous and mucous surfaces are often involved and obstinate conjunctivitis stomatitis, involvement of the auditory canals with furuncles and plugging from detritus add to the misery of the patient. Decubitus must be watched for in the emaciated and weak. Symptom from the throat and respiratory

tract are common, especially a tracheobronchitis. In patients who progress unfavorably a jaundiced tinge may appear but the liver is rarely palpable. There may be signs of nephrosis and a terminal exacerbation of infections, often a streptococcal pneumonia, may close the scene. Diarrhea is an obstinate feature of some cases and entirely absent in others.

In 1917 1918, 1919 and 1920 on the Mayo Clinic Service there were no cases with diarrhea, but in the 1922 epidemic all 5 cases of cutaneous reaction were accompanied by diarrhea, which in 2 cases was extremely serious and associated with such degree of ulceration in colon, sigmoid and rectum that one of the patients developed a rectovaginal fistula. From the bases of several ulcers an almost pure culture of streptococci was obtained. Examinations for other bacterial causes of colonic ulceration were negative. This, we take it, is only one of the evidences of the intervention of secondary septic infectious factors in the course, not to mention the etiology of exfoliative dermatitis occurring under treatment for syphilis. Michelson, for example observed streptococcus septicemia in fatal case of posttreatment exfoliative dermatitis.

A fatal outcome, when it develops, usually appears in the second stage of the dermatitis. In such cases, changes in the viscera indicative of acute arsenical poisoning are often found, as in the case reported by Latham. In other cases, acute fatal respiratory infections dominate the picture. In the later deaths in the third stage exhaustion, aplastic anemia, and septic complications combine to bring about the fatal issue.

Robinson and Roncheres have each reported gangrene of an extremity as a complication of exfoliative dermatitis in fatal cases, one with prodromal warning

An important consideration, leading in one case to a fatal termination, is that of the danger of tampering with focal infections during the course of the attack. In seven patients sharp flare-ups occurred in five following interference with a focus of infection the evidence tending to indicate that the action is indirect rather than direct. Tampering with foci of infection (tonsils, abscessed teeth) was responsible for death in one case which would have recovered without intervention and another patient was precipitated from a mild attack with prospective early recovery into the most severe and protracted case of Stokes Mayo Clinic series by dental extractions done on the ninth day of the dermatitis. Another case taught us the danger of opening a series of successive progressive infections during the attack of dermatitis. Subsequent cases (5) demonstrated, however the safety of removing foci of infection during rest periods and some weeks after the arsphenamine course Fig 201 is a graphic illustration furnished by the temperature chart of the dangerous effect of interfering with focal infections during the course of a dermatitis.

Fourth or Convalescent Stage —The signs that herald approaching convalescence are resumption of sweating which seems to be almost completely suspended, so far as visible perspiration goes, during the height of the attack improvement in appetite and spirits and decreasing irritability disappearance of chilling appearance of islands of paler skin, especially about the chest and over the knees decreasing scaling and thinner and larger flakes disappearance of edema and leathery thickening (lichenification) from the skin The face and extremities are usually the last to clear and the hair may completely fall out, before it and the nails come in again. For weeks after the patient is almost cleared up the feet will become purplish and edematous if the patient is about on them for several hours Itching is slow to disappear partly because the patient acquires the scratching habit, and maintains the

thickening and lichenification by rubbing and scratching more or less automatically rather than in response to definite itching. Pigmentation varying from a slight mottling to a deep bronzing, may persist for some time but ultimately clears up. Cannon and his associates (1942) have shown that poikiloderma like changes may follow arsenical dermatitis and result in permanent damage to the skin. At times the patient's complexion seems actually the better for the attack, but it is not uncommon for cutaneous irritability to persist for months and even years, expressing itself in patches of winter dermatitis on the legs or a seborrheic scaling in the scalp or on the chest. In such cases it is usually found that the patient was annoyed by dermatitis or had a seborrheic skin before the attack, and indeed that this was one of the factors predisposing him to his exfoliative reaction.

It cannot be overemphasized that patients who have once had the full fledged exfoliative dermatitic attack are the victims of a sensitivity to arsenicals particularly which will last in all probability for years, if not for life.

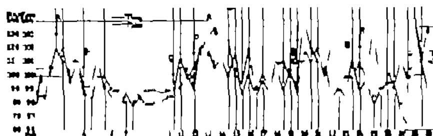

Fig 201.—Effect of interference with foci of infection on the course of postarsphenamine dermatitis: A, Fever accompanying extension of dermatitis after sixth arsphenamine injection. B fever subsiding, dermatitis improving; B–C dermatitis clearing up C, skin almost clear; tonsillectomy attempted patient refusing to permit completion of operation after tonsillar capsule was incised; febrile reaction D membranous tonsillitis developed, fever higher eruption previously almost gone, extending rapidly; E, eruption completely generalized, dusky livid hue, edematous, face swollen; E–F tonsillitis improving eruption somewhat less edematous and livid; F sharp chill, few râles at base of lungs, otherwise clear: skin exfoliating; G 8 teeth extracted, moderate reaction no change in skin H patient failing, scaling more pronounced steady decline until death five days later.

This is to be distinguished to some extent from the effects of the ninth-day erythema, but it cannot be too strongly emphasized that only under the most expert direction and with the greatest circumspection should any arsenical be exhibited to a patient who has once had a true exfoliative dermatitis.

The interplay of infection and allergy is well illustrated in many cases of exfoliative dermatitis One of our patients had seventeen relapses brought on by such episodes as nasorespiratory infection, relatively nontoxic drugs such as acetylsalicylic acid and so forth. Stokes and Kulchar' (1954) patients developed exacerbations after bismuth injection, exposure to goose feathers, and the development of cutaneous mycotic infection. The seriousness of this hypersensitivity is apparent from the fact that six years after an attack of exfoliative dermatitis which followed intramuscular injection of an arsenical, one patient was so extremely sensitive that single injection of mercury succinimide nearly provoked another attack, and the patient was likewise hypersensitive to iodide. It has been our experience that at least 50 per cent of patients who have had severe dermatitis must permanently abandon the intensive treatment of their infection. The unreliability of the patch-test for sensitivity should be recalled. It is also worth while recalling both the occasional response of exfoliative dermatitis to fever therapy and Simpson (1942) belief, and that of his coworkers, that exfoliative dermatitis is less frequent where fever therapy is employed in conjunction with chemotherapy While tryparsamide occasionally produces ex

foliative dermatitis, it is often a valuable alternate in cases of neurosyphilis. Serologic negativity may develop during an attack of exfoliative dermatitis, the basis for assumption regarding ecophylactic or protective effect. Epstein (1937) found these reversals to occur in about 60 per cent of his cases but Robinson (1913) believes that the rôle untoward reactions play in the cure or amelioration of the symptoms of syphilis or even in the reversing of a positive blood serologic reaction to negative if not without value, is, at best, negligible

The Prevention of Exfoliative Dermatitis.—No one who has had the opportunity to appreciate the misery expense and risk to the patient, or the strain on the physician, of a serious case of dermatitis will fail to realize that a gram of prevention here is worth many kilos of cure. Whenever a case of dermatitis occurs the physician should honestly and painstakingly search

Fig. 202.

THE ATTEMPT TO ABORT A DERMATITIS

1 All specific treatment instantly suspended
2 A complete blood count.
3. Sodium thiosulphate intravenously 0.5 0.75 1 Gm. on three successive or on alternate days for 3 injections may be tried. Vitamin C may be more effective
4 Additional well-recommended measures for alternative use
   (a) Bleeding (once) 200–400 cc. (Harrison)
   (b) Insulin, 5 to 10 units subcutaneously glucose solution 25 to 50 per cent 20 cc intravenously once or twice daily or on alternate days.
   (c) Calcium gluconate 10 cc of a 10 per cent solution intramuscularly or intravenously (very slowly) once daily or on alternate days, for 3 or 4 successive doses. (Karrenberg and Gerwig)
   (d) Quinine, 20–30 grains daily (Harrison)
   (e) Liver extract by mouth, intramuscularly (MacKee and Astrachan) or intravenously (Spethoff)
5 Removal of all surface irritants from the skin (mercurial ointment iodine etc)
6 Rest in bed, hospitalization preferred. Air-moistened room
7 *Avoid all chilling and keep respiratory infections* [illegible]*y*
8 A mild saline or alkaline laxative unless diarrheic Do not purge
9 High saline enema.
10 Fischer solution per rectum, 20-drop proctoclysis, [illegible] hours on, one hour off unless diarrheic.
11 Low carbohydrate, high protein and fat diet.
12 Starch bath if itching is severe followed by oily lotion (lime of olive oil and lime water equal parts) to be used only if no chilling or lividity
13 No tampering with focal infections.
14 No exposure to *erythema* doses of ultraviolet light

his record in the case and learn all that he can from it as to the prevention of such accidents. He will find however that even with the most meticulous precautions the complication is sometimes unavoidable Vigilant inquiry into the prodromal symptoms and the etiologic warnings contained in the patient's history as outlined in Fig 100, has none the less great preventive value

In view of the definite tendency for patients to separate themselves into reactors and nonreactors, those who show a persistent disposition to react whether with itching high nervous irritability repeated nitritoid reaction and repeated gastro-intestinal reactions should be regarded as potential dermatitis risks and treated with conservatism and under consultant advice if necessary No risks should be taken with pregnant women focal infection should not be tampered with if a cutaneous reaction has begun, local irritation

of a susceptible skin must be strictly avoided whether by innunctions or by applications of iodine especially and patch sensitization tests may sensitize the patient. (Beerman.)

The Attempt to Abort a Dermatitis.—A certain amount can be done to abort a threatened attack of dermatitis. Measures of known efficiency together with the most recent suggestions from the literature are included in Fig 202. We have often had the impression, however that "aborted dermatitis" especially cases in which sodium thiosulphate seems to have had miraculous effect, might, if allowed to run an uninterrupted course, have proved simply to be examples of ninth-day erythema. There is a steady march *from bad to worse*, an inevitability about the true attack of postarsphenamine exfoliative dermatitis which furnishes some of the really cheerless moments of syphilotherapeutic experience.

Cases which begin with a sharp chill, or chilly sensation and in which the dermatitis extends rapidly and early assumes a markedly edematous or oozing character with pronounced lividity can rarely be aborted and may in fact, be rapidly fatal. The patient who reaches his worst and begins to pass into the chronic phase by the end of a week or ten days will almost certainly make a good recovery In some patients the issue hangs in the balance for week after week and only the most skillful medical and nursing care brings them through. In settling down for the long siege, hospitalization is a great help, and special nursing practically indispensable, but the patient should not be exposed to the risks of moving to a hospital if avoidable once his condition is serious hence the desirability of hospitalization in the first place

Treatment of the Fully Developed Attack.—Some diversity of opinion exists with reference to the treatment particularly of the local phases of exfoliative dermatitis. In the acute phase the preventive measures of Fig 202 are in order As the case settles down to chronicity a choice between dry and wet methods of treatment, so to speak, may be made. Our experience opposes, largely on the score of the misery of the patient, the extended use of dry treatment and particularly the so-called "powder bath" if "wet" treatment can be had. Harrison, however recommends keeping the main surface of the skin dry with calamine lotion and calamine powder because the dryness antagonizes secondary septic infection. The bran bath is recommended by him when the scaling becomes too troublesome. An ointment of 2 per cent ichthyol in a bland base, such as rose ointment, is advised for the flexures, and may also be used on the face.

The Starch or Colloid Bath.—We have had better results from what might be called a wet method of treatment which consists in allowing the patient the free use though not the continuous immersion in a colloid or buffered bath prepared by suspending 1 to 2 pounds of powdered corn starch or laundry starch in the ordinary tubful of water In severe cases where hospitalization is possible, the continuous bathtub of full length with a temperature control valve (Fig. 203) placed in a suitable hydrotherapeutic unit is of much assistance. It is possible, however in a large bathtub in the home to carry out this treatment reasonably well, especially if the tub is so placed that it can be covered with rubber sheeting to keep the exposed parts of the patient from chilling

Certain details are of importance in the giving of the buffered bath. Oatmeal boiled to a porridge or thick gruel may be placed in a cheesecloth bag, this bag being then washed about in the water in preference to the use of

ordinary starch If there is much grease or detritus to remove one-half cupful of baking soda may be added to the tubful of water and dissolved in it before the patient enters the water In such a bath a dermatitis patient may soak for from fifteen minutes to one hour depending on his condition. He should not be overfatigued. O'Leary warns against the excessive use of the colloid bath as tending to produce waterlogging of the skin. While the patient is in the bath he may gently stroke himself clean or be stroked by the nurse using the flat of the hand without rubbing or scratching The water must not be hot but kept comfortably warm by adding hot water as the tub cools. Before putting the patient into the water the temperature should be tested with a bath thermometer 95° F being an optimum but a higher temperature sometimes being required on account of the tendency to chilling Debilitated pa

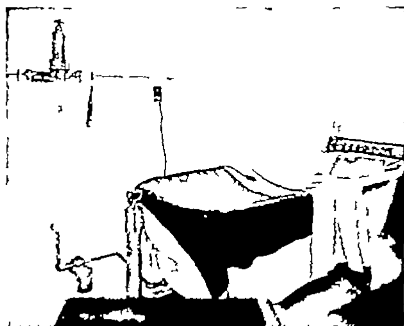

Fig 203.—Method of dressing the full-length tub for the colloid bath in treating exfoliative dermatitis.

tients should under no circumstances be left unattended. If the bath is warm an ice-cap on the head may be used but is seldom needed.

The moment the patient emerges from the bath he should be dried very rapidly by patting without rubbing and an oily preparation instantly applied If the patient is transported from one room to another or allowed to sit about for even a few minutes before the oily preparation is applied he is thereby made much worse. For this application rose ointment, plain or borated (2 to 5 per cent) or two parts olive oil, one part witch hazel water and one part lime water containing 2 drachms starch and 1 drachm glycerin to 6 or 8 ounces of the mixture, is satisfactory Antipruritics often irritate rather than help and even though the patient may demand them, should not be used.

Sterilization of hammock, sheets, towels, and cheesecloth bags when used is accomplished after washing by boiling in a solution of borax and washing soda, followed by thorough rinsing It is important to emphasize the necessity

for these precautions, for not only may the patient be severely infected by carelessness in this regard with the development of extensive furuncles and impetiginous lesions, but the attending nurses may acquire pyogenic infections of the fingers and arms. No bichloride, phenol, lysol, or other oily or irritant substance, however should be used in disinfection of the linen. The tub is cleansed by washing with lysol, followed by large amounts of hot water and then by vigorous scrubbing with a cleaning powder and rinsing with a bath spray and hot water There should be no odor of lysol about the tub when cleaning is completed. Systematic cleansing of this sort should be done daily soap and water being sufficient after the individual baths.

Additional Details.—Fig. 204 summarizes the detail involved in the management of a fully established case of dermatitis. If the case shows a distinct tendency to a pyogenic course, dry rather than wet management may be preferable. The fortification of general resistance by feeding vitamins (A and B) has at least theory to recommend it (halibut liver oil, yeast extracts) The daily administration of insulin and glucose throughout the course was the turning point in one of our patients and as in jaundice, helps to combat emaciation. Liver extract may also be used in accordance with the conceptions of Spiethoff and Milbradt and the experience of MacKee and Astrachan. Jenkins (1943) has tried histamine intradermally subcutaneously and intravenously from once in 1 to 3 days to three to four times a day (0 1 cc. of 1–1000 histamine dihydrochloride intramuscularly as the initial dose) He believes that the ideal results could be obtained by the simultaneous use of colloidal baths, histamine, ephedrine and phenobarbital. E Epstein in a controlled series found the method described in this text efficient. Local dermatophytic foci which may have predisposing significance (Stokes and Kulchar) may require conservative and consistent treatment.

Medicolegal Considerations.—It is well to bear in mind the medicolegal possibilities in a case of exfoliative dermatitis, and to make no unconsidered statements or permit others to make them.

Renal Reactions.—The mechanism and manifestations of renal reaction together with McFarland's conclusions from an extended experience with the behavior of the kidney under treatment for syphilis, are discussed in connection with the toxicology of the arsenicals and the heavy metals (pp. 200 218, 226 and 251) With the advent of bismuth there is a definite and gratifying reduction in renal reactivity to treatment. In combined treatment with moderation in dosage, reaction on the part of the kidney is almost negligible but should none the less be watched for by periodic urine examinations at intervals not greater than two weeks. Certain patients will tend to develop a treatment nephrosis. The susceptibility of the kidney to focal infection, giving rise to overloads on its excretory power is illustrated in Fig. 173 Wells and Sewell (1941) have shown that the combination of arsenical and heavy metal treatment and the hot weather (sweating) of the tropics lead to a toxic concentration of bismuth in the convoluted tubules—with resultant albuminuria but with normal kidney function.

Under routine treatment, therefore, one should not be too timid in the face of the occasional appearance of hyaline casts or a very slight albuminuria. There is a marked tendency toward spontaneous recovery from renal irritation even with the continuance of treatment, and attention to preventive detail usually does away with the necessity for any reduction in the intensity of treatment where intensity is desired or necessary The relative order of the

Fig 204

MANAGEMENT OF THE FULLY ESTABLISHED CASE OF DERMATITIS

1 Keep up nutrition by full soft diet and persuasion.
2. Keep sources of irritation and anxiety ay Systematic and sympathetic encouragement
3 Use every precaution t keep infections and carriers of infections, especially respiratory infections, ay
4 Nurses should wear rubber gloves, preferably elbow length, in handling patient and wash any exposed parts of their hands or forearms with tincture of green soap.
5 Keep bedding clean, changing daily
6 Give colloid bath two t *four times* day *ten to thirty minutes, according t strength* of patient. This is the best relief for itching Bathroom should be part of suit if possible and special care must be taken t avoid chilling or exposure Last bath at bedtime Optimum bath temperature 95° F but may have t be w rmer for chilly patients. Nurse must never leave patient alone in bath.
7 Grease the skin *at once* on drying (patting, not rubbing) after bath. Do this before leaving bathroom.
8 Lassar paste without salicylic acid, rose ointment, borated or not olive oil and lime water emulsion may be used t suit the individual case In some refractory cases goose grease is very acceptable later
9 Cover patient according t his wishes, t prevent chilling in bed.
10 Keep air in room warm (75° t 80° F) and moist.
11 Keep weight of bedding from feet by cradle and keep dependent parts elevated to control edema.
12. Discontinue Fischer solution and do not flood with fluids in the earl chronic phase or edema may recur
13. For the outbursts of oozing on face or extremities try bland et dressings (kept et, but not dripping) and bandages or mask.
14 Keep detritus removed by the bath, but trim skin tags from palms and soles ith scissors (don t allow patient to pull or tear)
15 Clipping the patient hair close makes cleaner scalp
16 Local infections (abscesses, furuncles, broken-dow lymph gland) must be tched for and promptly opened and drained.
17 Constipation in edematous patients ma be handled by catharsis, but in others is better dealt with by enemas, forced fluids and fruit juices, olive oil per rectum t be retained, and coarsening of the diet if tolerated.
18. For the conjunctivitis, zinc-boric solution, or if purulent, 10 per cent argyrol. Remove excess from lids to prevent local argyria.
19 For the lips, borated rose ointment. Keep the mouth clean and take out all removable dentures. If gingivitis and stomatitis are severe, treat as for mercurial stomatitis. Dental attention t gum pockets is very helpful.
20. Syringe out ears with arm boric solution occasionally and have excessive detritus removed instrumentally without trauma. Watch for furuncles.
21. W tch for decubitus and make every effort to prevent it, although it is not always preventable
22. If diarrhea develops, use hot saline irrigations, provided blood and pus are present or ulcers can be recognized proctoscopically
23. During convalescence reduce the scratching habit.
24. During convalescence increase the food intake and favor perspiration without chilling
25. I protracted cases, with persistence of patches, short general exposures t ultraviolet light (quartz lamp) and intramuscular injections of the patient own whole blood (10 cc. once weekly) may be helpful. Roentgen-ray unfiltered, in small doses under expert direction may be quite effective
26. The use of insulin and glucose, calcium, sodium thiosulphat vitamin C and of liver extract is given on pp. 363–368.

available drugs in irritation-producing qualities should be borne in mind, the iodides and arsenicals and tryparsamide being least irritating bismuth next and *mercury* the most troublesome of all. Temporary discontinuance of the

most irritating drug with mild alkalinization and a bland diet without alcohol tends to control irritation in a short time. The nephrosis tends to recover spontaneously within six months or a year on complete cessation of treatment. Patients with chronic nephritis are undoubtedly more reactive to treatment than normal persons but seem to make quite as satisfactory recoveries on suspension of treatment. The less irritating combinations, such as arsenical and bismuth should be used in cases of this kind Approximately one month is the proper time to allow for the urine to return to normal after stopping noncumulative heavy-metal treatment for syphilis. Renal hematuria is a serious sign of intolerance, and treatment should never be pushed this far Anuria, when it occurs as a complication of treatment is almost invariably the sequel of acid arsphenamine administration but may occur even after a single dose of a bismuth compound (thiobismol, Eitzen, 1937) Fischer's solution intravenously (see p 387) has provided thus far the only successful and indeed rational treatment. Decapsulation of the kidney can, of course, be considered but is rarely either feasible or practiced.

Pulmonary Reactions and Complications.—These have in part been considered under embolism (p 393) Iodide asthma an acute bronchial spasm with wheezing râles all over the chest, possibly due to pulmonary edema, occurs at times with intravenous sodium iodide administration and is at once relieved by 10 minims of 1 to 1000 epinephrine solution subcutaneously The possibility of acute edema of the larynx should be borne in mind, though we have never seen a case in thousands of injections. Precaution in not administering the drug to patients, whose tolerance of iodide by mouth has not been demonstrated, apparently eliminates this as a practical consideration. The pulmonary complications most frequently produced by the arsenicals are part of the mechanism of red blood cell agglutination with the formation of thrombi in nitritoid-like reactions already discussed. The symptoms are included in those of the nitritoid crisis and those of acid arsphenamine administration (pp. 391 400) Occasionally however the lung symptoms seem to be singled out for special prominence, and a sense of constriction in the chest, which rapidly passes off when the injection is stopped, or dyspnea, may express either changes in pulmonary blood pressure, transient flooding of the lung with minute erythrocytic emboli, or an actual arsphenamine asthma. All patients who have definite but not localizable pulmonary symptoms during injection should be kept in bed and under observation for two days to identify the possible bronchopneumonia which may ensue. Patients who cough severely *after any form of treatment should likewise be kept under observation for* from one to two days and inquiry made as to possible signs of embolus. These include pain in the side with a friction rub detectable on auscultation, or in the case of silent central emboli, rusty or blood tinged sputum. Arsphenamine asthma is a rare condition, usually accompanied by urticaria, coming on from twenty minutes to four or five hours after injection, and promptly relieved by epinephrine. It is apparently a true idiosyncrasy and argues a perhaps dangerous degree of sensitization. Great reduction in the next dose with the preliminary administration of ephedrine is the logical procedure.

The prevention of pulmonary accidents consists first in carefully checking the possibility of existing respiratory infection at the time of injection by questions, temperature report and physical signs second, in the use of neoarsphenamine or mapharsen if there is any intrinsic disease of the lung parenchyma, third, in the proper technic to avoid embolism, administration of in

available drugs in irritation-producing qualities should be borne in mind, the iodides and arsenicals and tryparsamide being least irritating bismuth next, and mercury the most troublesome of all. Temporary discontinuance of the

tient to enormous doses of adrenalin was remarkable and several times we thought the tide turned in her favor. The dosage of epinephrine should be large enough to produce an effect; not less than 1 cc. of 1 to 1000 solution intravenously given slowly. It may also be given intramuscularly and is perhaps safer in this way. If there is response, larger doses may be given subcutaneously 1 or 2 cc. every two or three hours, the dose being reduced and interval being lengthened with the response. One fatal case showed definite response to doses as high as 5 cc. subcutaneously.

If seen very early during the stage of stupor or depression, before delirium or convulsions set in, the outlook is fairly good. In cases seen *in extremis* the technic of dehydrating the cortex, as in delirium tremens, by spinal drainage and the intravenous injection of 100 cc. of 10 per cent saline solution, may be tried. Undoubtedly a number of cases have passed as examples of hemorrhagic encephalopathy which have accompanying manifestations of hemorrhagic purpura with aplastic anemia and agranulocytosis. In these cases the outlook is very much worse and a blood count therefore should be taken in the effort to evaluate the situation. Lees reports obtaining blood from lumbar puncture at three different levels in one of his cases.

Differential Diagnosis.—The differential diagnosis of arsenical encephalopathy must be interpreted in the light of cerebral therapeutic shock (Herxheimer effect) and the various encephalitic manifestations involved in the differential diagnosis of neurosyphilis (p. 1018). Confusion with the convulsive seizures of general paresis, with status epilepticus, with syphilitic encephalitis, and with fulminating encephalitis of the epidemic type is possible. The administration of an arsenical injection within three or four days preceding the onset of the attack, is a suspicious circumstance and an epinephrine therapeutic test should be applied if the patient is not in convulsions. A spinal fluid examination should be made if there is no choked disk, and sodium thiosulphate may be given, though with what effect is, of course, uncertain. A previous history of seizures, due consideration of any apparent alcoholic factors in the case, apoplexy, fat embolism and so forth, must of course be had.

Therapeutic shock effects are particularly prone to manifest themselves in the nervous system when active lesions are present, and without doubt a proportion of cases of postarsphenamine myelitis, encephalitic syndromes following large doses of arsenical in patients with syphilitic encephalitis, cortical leptomeningitis, and diffuse vascular processes of a syphilitic type may confuse the picture. The cranial nerve injuries resulting from therapeutic shock in basilar meningeal and nuclear lesions when an arsenical has been administered suddenly in large dosage, are, of course, less suggestive of the encephalopathic picture. The majority of Herxheimer effects tend to appear after the first injection, so that their delay until the third, fourth or fifth injection argues rather for an arsphenamine complication.

Peripheral Neuritis.—Following prolonged series of the arsenicals and after massive dosage, prickling of the hands and feet with definite peripheral neuritic changes in occasional instances may be noted, but it is really remarkable how rare these effects are with the ordinary systems of therapy. Ehrlich early described the complication and Beeson observed a severe grade of peripheral neuritis with exfoliative dermatitis. Moore and Keidel have seen similar examples. We have known prickling of the hands and feet of neurocirculatory origin ("acroparesthesia") or from other causes of neuritis, to lead to considerable perplexity and a diminished intensity of treatment in early syphilis when the symptom was, so far as the arsenical therapy was concerned, without significance. The treatment in arsenical cases is that of all arsenical compli-

cations of arsphenamine administration In the pseudoreactions attention to focal infections, infra-red radiation, abstinence from alcohol and investigation of other drugs and causes of neuritis, should be made.

Peripheral neuritis in the massive dose arsenotherapy of syphilis by in travenous drip reached 35 per cent when neoarsphenamine was used but fell to 1 6 per cent with mapharsen. Part of the improvement was attributed to the employment of veins of the forearm instead of those of the cubital space with the resulting greater freedom of movement.

Hysterical seizures occasionally complicate the treatment of syphilis, as mentioned on page 411

Reactions Involving the Bones and Joints.—The arthritis and myalgia of mercurial and, to a much less extent, bismuth therapy and the occasional examples of arthritoid arsenical reaction with fever and erythema, are, we believe, attributable especially to the lighting-up of foci of infection in the body and not to the drug as such. Mercurial arthralgia particularly seems to have a definite association with bad oral hygiene and we cannot recall having seen it in patients under satisfactory prophylactic conditions. It may be neces sary to stop treatment in such cases until the focal infections are cleared up Salicylates give temporary relief Patients with multiple arthritis often cannot tolerate mercury at all by inunction, which is the particular form of admin istration most likely to give rise to arthralgic reactions, though they may be able to take it by mouth or intramuscularly Arthralgia may form part of the prodrome of infectious epidemic jaundice, together with urticaria (p 249) The jaundice usually begins about two weeks after the arthralgia. Bismuth grippe usually correctly identified only after it has been repeated once or twice, responds only to discontinuance of the drug

Reactions in Special Sense Organs.—Mercury and bismuth have no known effects on the special sense organs. The intravenous administration of mercury oxycyanide may be accompanied by a complaint from the patient that he smells bitter almonds and the odor during the intravenous administration of an arsenical has been mentioned A critical patient has assured one of us (J H. S) that colloidal mercury sulphide intravenously gives a definite sweetish taste.

The optic nerve, formerly regarded as a peculiarly vulnerable point (*cf* Skirball and Thurmon, 1935) in trivalent arsenical treatment is, we believe only occasionally affected by the drug *per se* (see p 264) DeSchweinitz has repeatedly emphasized his impression of the fibrous changes induced in the *eye under arsenical therapy of ocular conditions, but this is rather an aspect* of therapeutic paradox than of drug reaction as such. All treatment for syphilis has a disagreeable trick of hurrying into total blindness or total deafness patients with lesions of the second or eighth nerve of the atrophic type, but it is very difficult under these circumstances to feel assured that the effect is not that of therapeutic shock or paradox rather than a reaction to the drugs employed, as such We have, however so frequently seen this undesirable sequel to trivalent arsenical therapy in primary optic atrophy that we hesitate very much in the use of the drug, preferring rather to open treatment with bismuth which, at least so far as our experience goes, has shown no such effects. We have also seen ill effects follow a trivalent arsenical given to pa tients with nerve changes associated with high myopia in the absence of syphilis, so that we believe that the drug may be injurious to the optic nerve as such. In neurorecurrence involving the eye, mercury succinimide intra

muscularly four or five times a week with sodium iodide intravenously will produce a sufficiently rapid effect to make the use of the trivalent arsenicals unnecessary at least at the start. Injuries to the optic nerve produced by the pentavalent arsenicals (*e.g.* tryparsamide) are discussed on p 1045

Therapeutic shock, as has been stated, occurs in all acute processes in the eye when treatment for syphilis begins, even, paradoxically when there is no syphilis present, as in nonspecific therapy (see p 155) Hemorrhages into the vitreous may be precipitated in patients who have had them before, and a nonspecific uveitis may show a marked flare-up with subsequent improvement. A warning should be given relative to the importance of inquiry into ear symptoms before the first injection of a trivalent arsenical is given, particularly in early syphilis, for the effects of therapeutic shock in such cases are apt to be permanent and disastrous. The other cranial nerves have, in our experience shown no intrinsic drug reactions, whatever

CHAPTER X

TREATMENT PLANNING LATENT SYPHILIS AND OTHER COLLATERAL ASPECTS AND SPECIAL PROBLEMS

The treatment of individual manifestations of the disease is taken up in the appropriate chapters, but the whole subject needs to be pinned together by a treatment map such as is attempted in Fig 205 The rapid development of a "public health" point of view towards syphilis has emphasized for treatment purposes the division into infectious and noninfectious" stages. Treatment to noninfectiousness is a public health conception for which as yet, precise definition is impossible notwithstanding urgent demand. It can best be met, for mass action purposes, by considering the first four years of an infection of known duration as an over-all period of infectiousness, and by treating the disease within that period with maximum intensity for radical cure rather than for the mere abolition or prevention of infectiousness. The noninfectious period (the quotes signify the relative character of such a designation) covers the period from late latency to the end of degenerative manifestations or of life and is largely a period of individualization as distinguished from scheduled or system management. Late latency arbitrarily now regarded as beginning with the fourth year of known duration, is the last outpost of systematization and is dealt with in present practice by methods short of the radical but systematized and prolonged to secure all the advantages possible under the various conceptions of treatment effect, as a species of 'life insurance" protection for the individual against progression of his disease or transmission to others The overwhelming practical importance of this sandwich of early and late latency between the obviously infective and intensively treated early syphilis, and the relatively noninfective and individualistically treated late syphilis, is the really numerically important category of the mass treatment problem today

Many times in practice the management of latency seems to resolve itself into the question "how to treat when there is nothing to treat"—or more exactly how to treat when there is nothing but a positive serologic test. The American studies of latency from the clinical standpoint have performed the service of providing blanket coverage on a quasi-empirical basis, for a vast *terra incognita* in the life story of the disease which on the one hand satisfies public health requirements by a reasonable attack on the infectiousness problem and individual requirements by reasonable and probably maximum protection against the degenerative eventualities for the individual on the other hand. Such blanket coverage simplifies in a not undesirable fashion the thinking of the syphilologist, who for years had confronted with uncertainty the anxious and sometimes angry question, If he has nothing to treat but a blood test, why treat him?

With this map in hand then one can place his selection of treatment methods on a sound biological, public health and individual clinical basis.

The Conception of Latency in Syphilis.—One should review at this point the material of Chapter I on the biologic course of the disease, with particular

Fig 203

A TREATMENT MAP BASED ON THE NEW STAGE CHRONOLOGY OF ACQUIRED SYPHILIS

(Replacing Primary Secondary Tertiary Quaternary Time relations are approximate and overlapping)

	Stage	Chronology	Characteristic.	Treatment Aim.
Infectious Syphilis	1 Seronegative primary	First 1 to 2 weeks.	Phase of maximum curability	
	2. Seropositive primary	2nd wk. to 2nd mo.	Phase of undeveloped immunity and relapse tendency	
	3. Florid secondary	2nd to 6th month	Phase of median curability with persistent seropositive tendency	Treat with maximum intensity by system, for medical cure
	4. Late secondary and recurrent.	6th month to 3rd year inclusive	Phase of relapse—inadequate treatment, special resistance	
	5 Early latent.	2nd to 4th y incl.	No manifestations.	
	6. Late latent.	4th year onward	Phase of benignity no manifestations, seroresistance, congenital transmission, progression.	Treat by special standard for "life insurance" to stop progression or transmission.
"Non-infectious" Syphilis	7 Late syphilis of special structures			
	a. Precocious tertiarism.	Harks back to (2), (3), (4)	Result of inadequate treatment, low resistance	
	b. Late destructive recurrences.	Harks back to (4).	Mostly skin, bones.	
	c. Special sense organs, especially eye.			Treat by individual methods of graded but adequate intensity to repair damage stop progression, "cure" if possible.
	d Inflammatory skeletal syphilis.		Gummas, osteitis, osteomyelitis, etc.	
	e. Early cardiovascular syphilis.	4th year onward.	Early aortic change peripheral accidents.	
	f. Asymptomatic and early neurosyphilis, preponderantly meningovascular	1st month onward.	Abnormal spinal fluid, slight clinical changes.	
	g. Late cardiovascular syphilis.	10th year onward.	Advanced aortic valvular and aneurysmal disease.	Treat individually avoiding shock and paradox, for symptomatic relief, and to stop progression.
	h. Late neurosyphilis, preponderantly parenchymatous and degenerative.	4th year onward.	Tabes, paresis.	

CONGENITAL SYPHILIS FOLLOWS THE CHRONOLOGY FROM (3) WITH EMPHASIS ON (7)

emphasis from the clinical side on the discussion of the Bruusgaard statistics and other evidence of a strong tendency to years of asymptomatic course terminating in trifling benign manifestations mere landmarks such as persistently positive serologic tests, or microscopic evidence of the disease recognized only at autopsy after death from other "normal" causes

Three tendencies have marked the development of thinking within the past decade on the essential nature of latency The first of these is the extension of the serologic test on the blood to the well individual, in contrast with the sick. This might reasonably be expected to expand immensely the inert asymptomatic, nonprogressive syphilis recognized, as well as that portion of such latency as was headed for future disaster From what we now know of the behavior of the disease, we reasonably expect the expansion in the direction of innocuous latency to be more rapid than in the direction of potentially disastrous outcomes of latency

A good cross-section of the latency problem in current syphilologic practice is afforded by the statistics of the University of Pennsylvania Hospital clinic for the five years, January 1938 to January 1943 inclusive. Of 1813 syphilitic admissions, 61 per cent were diagnosed as latent syphilis. Of the 1114 cases, 15.8 per cent were diagnosed as early latent syphilis, and 84.2 per cent as late latent syphilis. Of the 176 early latent cases, 21 per cent were diagnosed as seronegative latency and 79 per cent as seropositive latency Of the 938 late latent cases, 14 per cent were diagnosed as seronegative and 86 per cent as seropositive latency

It is therefore reasonable to suppose as far as treatment is concerned, that the amount of recognized latency really requiring treatment, as distinguished from theoretically will decrease in proportion to the whole, rather than increase. The question of whether or not to treat latency at all, and how much treatment to give it, may therefore be expected to sustain considerable readjustment in the coming decade The second tendency is for writers to become over-analytical, and to develop an esoteric terminology for a relatively simple matter The subdivision of latency into types always carries this danger with it. Where there is nothing to describe, the effort to describe it in many words may be confusing We have not therefore, at this point, introduced into our discussion of latency the subdivisions of Moore (1932, 1933 1937–9) including clinical, serologic and pathologic types. Whatever else it may be, latency must be syphilis, demonstrable as such by evidence acceptable to the critical mind In the direction of latency with negative blood serologic tests, it collides with the growing conceptions of cure. In the opposite direction *it collides with the inescapable fact that even death from syphilis may ensue* upon a state of complete serologic negativeness. Seronegative latency may be identified by history on the evidence of credible authority that the disease has existed, even though it is now silent by inescapable evidence that it has existed in the form of symptomatic or physical scars. Seropositive latency collides at the one extreme with the biologic false positive test reaction and our ignorance of the "reagin" mechanism at the other extreme with the undoubted existence over periods of years, even to the termination of life in its normal course if a totally irreversible serologic reaction unaccompanied by any symptomatic or physical sign of the disease.

It becomes apparent then, that latency is practically more a matter of what it may become, than of what it actually is, for as it is it is nothing so far as our clinical criteria of significant change are concerned. Latency is syphilis identified by some controllable and trustworthy evidence that the infection

is present but unaccompanied by any evidence that it is clinically active. Monosymptomatic seropositive latency is the largest single category in the group. It has been over-expanded to an unknown but probably large degree in the past, and one causing much concern in the present by the biologic false positive serologic test which has undoubtedly swelled the roll of latency by many persons who do not have syphilis at all but who on serologic findings have been diagnosed and treated. Until the syphilitic reagin can be tagged as to specificity by the identification of its precise nature and tests for its identity latent syphilis remains a parlous diagnosis capable of reflecting discredit on technical medicine and, in theory at least, injury upon the patient.

The process of establishing the existence of latency is outlined in Fig 206 To every individual investigated for the presence of latent syphilis, the fine-tooth comb of anamnestic and physical examination must be scrupulously critically and completely applied Broadly speaking the more detailed the examination, and the more expertly performed the better the likelihood that

Fig 206

TO ESTABLISH THE EXISTENCE OF LATENCY

1 Establishing latent syphilis as diagnosis includes
   ( ) Proving the presence of the disease
   (b) Excluding every clinical evidence of its activity except the serologic tests on the blood.
2. Proving the presence of syphilis includes
   ( ) The complete physical examination and history Turn t Figs. 12 and 13, Chapter II, keeping in mind the causes of biologic false positive tests, Fig 33.
   (b) Checking the validity of the positive blood serologic test. Turn t p. 63.
   ( ) Competent special examinations of the yes, the bones, the cardiovascular stripe (fluoroscopy etc.), the stigmatized structures (bones, teeth) for evidence of congenital or acquired syphilis, as indicated.
   (d) Examination of the spinal fluid.
   ( ) Study and examination of family and sexual contacts
3. If ( ) and ( ) under 2 show active syphilitic processes, the case is not latent.
4 Excluding all clinical evidence of activity means ( ) and (d) negative

THE BLUNDER OF THE (QUARTER) CENTURY—DIAGNOSING LATENCY WITHOUT A CONFIRMED BLOOD AND A SPINAL FLUID EXAMINATION

the disease will be identified, and more than one evidence of its presence be forthcoming If the evidence is other than a pathognomonic scar or such a fact as the giving birth to a syphilitic child, which in present knowledge automatically establishes the existence of syphilis in the mother the question arises as to whether the infection should be designated as active rather than latent. A positive blood serologic test of syphilitic origin is still accepted as presumptive evidence of the existence of a live" infection. It remains to be seen whether it persists after the extinction of the last spirochete—a question perhaps resolvable by ultraintensive therapy followed by quantitative serologic tests and with autopsy control. When we speak, therefore, of the positive serologic test in prolonged asymptomatic latency as a scar of the disease we are taking inferential license for the comfort of the patient and in recognition of the Bruusgaard and other experiential evidence of benignity When, in the examination of latent syphilis, detected by a positive blood serologic test, an abnormal spinal fluid is unearthed, the diagnosis of latency is dropped,

and that of asymptomatic neurosyphilis substituted because experience of the benignity and nonprogressiveness of a neurosyphilis defined by an abnormal spinal fluid pattern is small and the evidence in favor of activity and grave progressive tendency overwhelmingly the greater Nonetheless it is not inconceivable that time will justify the position that there is a true latency with at least a positive serologic test on the spinal fluid, and perhaps abnormal protein levels and an abnormal colloidal test. The presence of vascularization in the cornea on slitlamp examination the identification of proliferative change, the sequel of old periostitis and a number of other residues of syphilis identifiable in the examinations outlined under Fig 206 carry with them this inevitable clinical uncertainty as to whether they are the scars of an old or dead process, or the wave traces on the bodily shore of what may prove ultimately to be an inevitably though intermittently advancing tide of syphilitic complications and sequelae.

Since the decision as to what shall constitute latency and what its ultimate meaning or destination may be carries these inevitable elements of uncertainty the treatment policy both from the public health and the individual standpoints must inevitably lean towards treatment, and not away from it. The decision not to treat in the presence of evidence that a syphilitic infection has existed, even though now quiescent, is a critical one and not to be lightly undertaken. The inclination must be to treat the infection if

1 The latency is of undetermined, but presumably relatively short duration
2. The individual is young or has a reasonably long life expectancy
3 There has been evidence of a trend towards infectious recurrence.
4 The patient is a woman, who, regardless of social status, may still become pregnant, thus endangering the child.

On the first of these considerations, it may be assumed for arbitrary mass classification purposes, that most syphilis is acquired before the age of thirty or even twenty-five. An infection identified at age thirty two may be assumed depending somewhat on the life history and make-up of the individual, to be an early rather than a late latency since the tolerance of treatment at this age is good, the decision will lean towards intensive curative measures, perhaps, rather than towards a system for "life insurance" In a patient of fifty it may be assumed that the latency is of at least twenty years duration the life expectancy at best not more than twenty years infectiousness over with the likelihood of progression reduced to lowest terms, and the necessity for intensive measures therefore nil and for routine life insurance" therapy minimal if not actually nonexistent. On the other hand, in an infection acquired at age sixty latency at age sixty-five has more of the qualities of early than of late latency from the public health if not the individual standpoint, and though the life expectancy may be short, the danger of transmission may be considerable Treatment, accordingly leans towards maximum intensity rather than routine "life insurance." At this point one of Moore s tabulations, essentially an astute guess is of great suggestive value.

Moore further estimates, to quote his own words, "In those infected less than five years, the probable outcome without treatment may be assumed to be essentially the same as for early syphilis itself i.e 25 per cent spontaneous cure, 25 per cent continued latency 25 per cent probability of late allergic gummatous lesions 25 per cent risk of cardiovascular or neurosyphilis.

Moore has pointed out the importance of race and sex in the prognosis of latency rating Negroes as much more prone to develop late lesions, especially of the cardiovascular type, than whites and women notably less likely to develop manifestations of the disease than men. The Negro woman has a particularly benign and prolonged latency which however must be matched against her established greater tendency to infectious lesions early in the course of the disease. It may be quite safe according to Moore, to withhold treatment completely from a woman past the menopause, while to a man of comparable age it should be given. Moore well emphasizes the principle reiterated in this discussion, that generalizations about latency have mass rather than individual application.

In the past twenty-five years, the pendulum has accomplished a complete back-and-forth swing from an original disposition on the part of older physicians to minimize latency and for the patients gladly to accept the policy of noninterference, through the day of the younger generation of physicians who reacted to the positive serologic test as a bull to a red rag In the middle

Fig 207

PROGNOSIS OF LATENT SYPHILIS (UNTREATED)

Duration of Infection	Probable Percentage of Spontaneous "Cure or Continued Latency	Probable Percentage of Future Lesions
0–5 years	60	40
5–10 years	70	30
10–20 years	80	20
20–30 years	85–90	10–15
30 years	90–95	5–10

(J E. Moore, personal communication)

ten years, the patient in his turn alarmed by gradually spreading knowledge of the prevalence and seriousness of the disease, accepted treatment with alacrity and pursued it often with insistence. The combined effect was expressed in a *furor therapeutica* which justifies the aphorism of Fig. 208 to the effect that most latent syphilis today is underexamined and overtreated. Now the pendulum is again swinging towards conservatism the disposition is towards moderate rather than maximal treatment, and the punishment of latency for being caught with a positive blood test is being reduced and in more cases, remitted altogether

Active Process *versus* Residuum.—The decision as to whether one is dealing with an active syphilitic process or a residuum is sometimes extremely difficult and critically important because if the structure involved is vital the process may be more advanced than clinical signs indicate, more subject to therapeutic shock and paradox which alter the mode of approach. Here again, the wiser policy is to lean towards the diagnosis of active infection rather than the diagnosis of latency This consideration has probably led to such anomalies in diagnostic terminology as "latent cardiovascular " "latent

neurosyphilis" and so forth. There is of course no object in treating a patient for a scar such as a fixed pupil or an absent knee-jerk which cannot as a rule be affected in any way On the other hand, the mixture of scar and active inflammatory process which a case often represents can be materially benefited—the relief being proportional to the amount of active inflammation. For example, corneal vascularization in an interstitial keratitis offers little outlook for improvement but if any evidence, even the slightest, of activity in the form of punctate infiltrates can be found the response to treatment may be surprising In such a case the decision to treat the patient for active syphilis and so to diagnose it is wiser than to accept latency as established and withhold treatment for conservative reasons or inertia. Such situations in general are saved by the principle of leaning toward treatment, and treatment for "life insurance" previously enunciated In such cases, the decision to treat the patient for syphilis may rest entirely with a specialist in another field, as for example early manifestations of involvement of the aorta, short of symptomatically demonstrable early aortitis. This field in particular is critically important, and the *shortcomings of clinical recognition of aortic syphilis* have been amply set forth in the classical work of Moore Danglade and Reisinger in their comparison of clinical and necropsy observations on 105 patients Few diagnoses are more risky than that of latent syphilis in the presence of even the slightest recognizable evidence, clinical roentgenologic or other of abnormality of the cardiovascular mechanism with a fair presumption of the presence of syphilis. (This work is subsequently referred to in the chapter on cardiovascular syphilis.) In some cases, such as retrobulbar neuritis, recent eighth nerve deafness, Bárány syndromes in syphilitic patients, persistent subjective symptoms in neurosyphilis such as lightning pains and headaches, and even constitutional subnormality without localizing signs, it may be desirable to treat what would otherwise be called a completely latent or "burnt out" infection because of the possibility of benefit. This is not a therapeutic test to establish the existence of syphilis for the diagnosis may be perfectly apparent, but a test of the treatability of what would otherwise be called a latent or inactive infection. In all such cases, treatment once begun must be carried to completion in accordance with a reasonable modern standard.

The Treatment of Latency —Because of its close relation in present-day practice to the more intensive treatment of early and potentially infectious syphilis, the modern optimum system for the treatment of latency is discussed in Chapter XIV

Irrespective of the treatment itself four principles deserve emphasis here. First, it is unjustifiable to disturb immunity relations in a patient with a latent *infection unless treatment can and will be carried far enough to block* the likelihood of induced allergy particularly from the arsenicals, and reactivation of the infection by short courses, inadequately followed through Milian has been particularly emphatic in his objection to undertreatment, not however particularly in the field of latency to which nonetheless, many of his conclusions might easily be applied. Treatment of the latent patient by opportunistic management following surgical operation in which the syphilis casually recognized as a possible factor in the situation receives a modicum of unwise attention in the form of a few "shots" is particularly undesirable. From what we know of the behavior of the arsenicals, this is a method of stimulating rather than retarding the course of the infection in an unknown proportion of patients.

A second principle applicable to the treatment of latency is that of beginning treatment with a heavy metal rather than an arsenical. With mapharsen this objection is perhaps less significant, but it is nonetheless a wise concession to shortcomings in examination and in the appraisal of the activity of the process, to begin by "preparation" methods with a heavy metal appropriate to one's estimate of the weakest spot in the situation rather than to run the risk of therapeutic shock, remote though it may seem.

A third principle is to close treatment with a heavy metal rather than an arsenical in order to leave an absorption depot and prolong effects for the protection of immunity. In fact, it has been in latency that the principle of

Fig. 208.

SOME DON'TS FOR LATENCY

1. Don't call patient latent on the basis of casual inspection and arm-chair examination. Distinguish between actual and spurious latency.
2. Don't decide the latency of case without examination of the spinal fluid and the cardiovascular mechanism.
3. Don't neglect any opportunity to secure base-line examination of the patient with syphilis early in his infection. A negative examination may be as valuable as positive in latent and later years.
4. Don't lose sight of seronegative latency especially in women who have had or may have children.
5. Don't forget that the prenatally infected child is presumptive proof of its mother's latent infection. Examine children as well as parents.
6. Don't lightly authorize pregnancy in latent syphilitic women. Insist on treatment.
7. Don't pound latency indiscriminately with intensive treatment. Consider the objective, the age, and time factors.
8. Don't begin the treatment of latency with an arsenical. Prefer bismuth, or even mercury and iodide.
9. Don't disturb immunity relations in latency with few shots of anything, especially an arsenical. If once begun for good cause follow through and end with heavy metal.
10. Don't treat even the most eligible and willing latent patient beyond the standard for early syphilis (p. 630). Refuse to be party to robbery or aggravated assault and battery even in the name of positive serologic reaction and the patient's demand for pure blood.
11. Don't casually withhold treatment because the patient "looks well"; realize the seriousness of putting him purely on his defence mechanism.
12. Don't dismiss the latent patient as "cured." Reexamination at intervals will, with expert assistance, compensate most errors of judgment in time.

MOST LATENCY IN SYPHILIS TODAY IS UNDEREXAMINED AND OVERTREATED

periodically renewing the patient's supply of heavy metal, so to speak, has led to the "course-a year" principle, indefinitely prolonged, which has been slowly gaining in popularity since the publication of the Cooperative Clinical Group reports.

A fourth principle and, in some respects, the one most abused in present day practice, opposes the year-in year-out pounding of the seropositive latent case in response to the physician's serology-bound conception that he ought to be doing something as long as the blood test is positive, or the patient's neurotic self-condemnatory feeling that he will never stop treatment until his blood is pure. The adoption of a reasonable standard of protective treat

ment will perhaps do away in time with the excesses and abuses which now constitute so serious a drain on treatment resources without corresponding advantage to the patient.

Observation Throughout Life.—Our present conception certainly permits us to believe that latency may eventuate in spontaneous cure. On the other hand this is wishful thinking rather than a fact established by autopsy protocols and experimental evidence Accordingly it is inadvisable to give the treated latent patient the impression that he will be cured in the strict sense by our intervention and he should be impressed with the necessity for *maintaining a reasonable schedule of periodic reexamination all facts dis-*

Fig 209

WHAT TO SAY TO THE SEROLOGIC "PICK-UP"
(The Patient Identified by Routine or "Survey" or Premarital and Prenatal Blood Tests)

1 Think before you speak. Remember a single positive blood test is not a diagnosis; recall the possibilities of biologic false positives, repeat the test; then recall that it does not define or describe the type of syphilis. That must next be delineated Do a complete physical examination get a complete history
2 Be tactful and cautious. Gauge the mental and emotional status of your patient, gain his or her confidence explain the importance of proving or disproving the presence of the disease your approach should be as follows—

3 Cheer up! It may not be true Even if we do find you have the disease it might be worse Let us approach the problem together
4 Did you ever have a blood test before? When. Who took the test? Was it positive? Was it repeated? What did you do about it? Any treatment? Who gave it? About how much?
5 What diseases and infections have you had recently? Vaccinated sore throats, colds, etc ? Try to give the dates.
6. Have you actually to your knowledge had syphilis, been told you had it; been treated for it? Give us the facts for your own sake
7 Tell me about your family—father mother brothers, sisters your sex contact and habits.
8 Are you, or have you been, married? Contemplating marriage? Have a sex partner? If you contemplate marriage or other grave commitments, better postpone them for three months. Expose no one sexually or by intimate contact until the situation is clarified If you are married, we should test your wife and children, but only after we have raised a strong presumption that you have the disease
9 Do not start treatment in a panic for a disease which you may not have Have a competent investigation made and see where you stand
10 Avoid pregnancy or the likelihood of becoming pregnant until the question of your having the disease is answered. If you are pregnant, a prompt decision on this matter is imperative lacking which it may even be advisable to assume the presence of the disease and undergo treatment to protect the baby Do not procure an abortion.

closed throughout life This need not of necessity include reexamination of the spinal fluid which according to Cooperative Clinical Group investigation once negative, is likely to remain negative On the other hand, a latency reduced to the seronegative state by treatment needs serologic as well as clinical controls. If especially in an early latency a blood test is negative for as long as a year and then becomes definitely and repeatedly positive (to be distinguished from the up-and-down or see-saw of partial positives and negatives in some latent cases after treatment) a reexamination of the spinal fluid is indicated. In the light of what we now know of the progression of cardiovascular syphilis under the mask of serologic negativeness or the see-saw

fluctuation of negatives and partial positives, it is also essential to have a fluoroscopy of the cardiovascular stripe an electrocardiogram, and if possible, a skilled interpretation of the physical signs and symptoms of early cardiovascular disease, at least once in five years, during latency no matter how prolonged. It is a fair presumption that if nothing has appeared by the end of the first decade, nothing is likely to appear but it is by no means a safe assumption, where the greatest safety for the individual is desired. In all advice to latent patients under observation, the anamnestic inquiry and the physical examination should be as conscientiously performed as the original study the interval between such checks should not exceed three and perhaps even two years and some thought regarding the contributory effects of over strain and trauma in the patient s life should accompany the advice covering the interval to the next examination.

The Cooperative Clinical Group studies of the treatment of latent syphilis, while they do definitely support the thesis of leaning towards treatment rather than away from it, contain some rather surprising evidences that once late latency at least is established, it makes little difference what one does, the patient comes out all right. For example, the satisfactory results under a wide range of treatment, from little or nothing to much arsphenamine range close around 50 per cent, but leap to 95 per cent when little or no arsphenamine but much heavy metal was employed (small number of cases) The result in one of the cooperating clinics on patients treated with heavy metal for years, without any arsenical treatment, tended to indicate that the prolonged use of heavy metal after all is what gives ultimate satisfactory results in latency This raises directly the question of treatment throughout life which was informally the vogue in the days of mercury and iodide by mouth, sustained a set-back as the toxicity of the more intensive methods and the newer drugs became apparent, and is now in process of revival as a treatment concept with the demonstration of the relative innocuousness of bismuth. Therapeutic "pecking" with "a course a year may now be accepted as good practice and insofar as it gives both patient and physician a feeling of assurance and prevents the development of syphilophobia and neurosis under the "observation throughout life concept, it may be conceived as desirable practice. In the relatively long heavy metal sessions of the standard treatment of latency subsequently discussed, a tapering off in the form of a course a year for from three to five years, following the completion of the formal requirement, is not unreasonable, though we are not as yet ready to subscribe to the conception of a course a year" even of bismuth, throughout life.

Latent Syphilis and Pregnancy.—While the treatment of syphilis in pregnancy is more fully discussed on page 1148, it is proper here to point out that apparently latent syphilis is one of the most important and most serious sources of the prenatal infection of the child For that reason, all considerations concerning the women with latent syphilis tend to revolve about its relation to her childbearing age and capacity For the diagnosis of syphilis in the woman an examination of her children is often necessary as has been said. The syphilitic child is *ipso facto* evidence that its mother had the disease, and the presumption is that, if living she still has it. Women with latent syphilis who may become the mothers of children should be treated in anticipation of conception and during pregnancy with all the judgment but nonetheless with all the determination that the occasion may require. The studies of the Cooperative Clinical Group, with Moore as spokesman show unmistakably how

serious is the toll in injured and infected children that the latent infection in the woman takes. Treatment of the latent syphilitic mother during pregnancy regardless of the amount, increases fourfold from 16 to 65 per cent the chance of obtaining a normal baby

Active Benign Syphilis.—The management of benign but active *syphilis* is a step beyond the problem of latency for the obligation to treat the patient is more apparent. At the same time it is important to keep fundamentals in mind, and to avoid exchanging a benign lesion and an effectively working defence mechanism, for some serious loss of resistance and a flare-up of dangerous proportions. An examination of spinal fluid and cardiovascular system is in order especially in those under sixty The patient who presents only trivial lesions of the bones and skin four or five decades after infection, should not be pounded with the heavy artillery of modern treatment. In such cases it is even distinctly risky to use the arsenicals because of their allergy-producing properties. Resort may well be had in such cases to mercury or bismuth (Sobisminol) by mouth and iodide to slightly more intensive mercurialization or to intramuscular bismuth therapy (iodobismitol) instead. On the other hand, in earlier life the appearance of even benign lesions must be the signal for thoroughgoing treatment and prolonged observation.

THE FIXED POSITIVE SEROLOGICAL TEST IN TREATMENT

Fixed positiveness or serological fastness has been discussed from the diagnostic standpoint on page 100 Chapter IV The essence of a fixed positive test is its failure to become negative under prolonged intensive treatment Few outcomes *more completely discourage and puzzle the conscientious* and well-meaning physician and patient.

Classification of Serological Fastness.—Four types of serological or reagin fastness or fixed positive Wassermann tests can be recognized in clinical practice, as follows

1 Fixed positive sequels of inadequate or ineffective treatment of early syphilis.

2. Fixed positives representing visceral, vascular and nervous system disease.

3 Reactivation of weak or partial positives which become strongly and irreversibly positive after treatment.

4 Monosymptomatic irreversible positive serological tests, in the absence of all other signs of the disease usually occurring in late latency and usually devoid of serious prognostic significance

By way of general discussion of these four types, it must be pointed out that the positiveness and the persistence of a serological test is a function of the technic of serological procedure employed. With the introduction of increasingly sensitive and yet specific modifications it is possible that a large proportion of established syphilis regardless of treatment, can be found to carry a partial or even a strong positive by the sensitive procedure, throughout the larger part of life. It is apparent, therefore that serological fastness is a relative matter at best.

Attention has also been called in the literature t the fact that ven strongly positive serological tests, if carried out quantitatively t the proper point, show variation and definit im provement under treatment when such improvement does not ppear in the routine test as performed for diagnosis (Coleman, Casselman, and Patterson) Quantitative procedure also shows many persistent seropositives of relatively low titer Spontaneous nd inexplicable vari

tions in the serological tests of patients with supposedly fixed positive Wassermann reactions observed over a period of years have been recorded by Gougerot and Peyre who found several such cases completely negative to repeated testings over periods of months in the course of many years of what would otherwise have appeared to be absolute serological resistance. Some of the up-and-down see-saw of fixed positive serology is of technical origin.

Fig. 210

SOME FUNDAMENTAL FACTS REGARDING SERORESISTANCE OR FASTNESS FROM THE TREATMENT STANDPOINT

1. **Seroresistance has increased** with the increasing sensitiveness of tests (Eagle 1937—100 per cent serofast in 1937 would have been 70 per cent in 1920, 28 per cent in 1907).
2. **The normal course of the reagin curve** is slowly downward with undulations and an ultimate low titer. The longer latency is observed the less seroresistant residue remains.
3. **Not knowing what reagin is,** we do not know outright when to treat its presence as active disease, when a scar.
4. In general, then, serologic fastness is a **sheaf of laboratory reports** (O'Leary) subject to therapeutic interpretation in terms of time and other findings.
5. In early syphilis it is serious, presaging relapse, infectious and otherwise, cardiovascular and neurosyphilis. In late syphilis, once visceral, cardiovascular and neurosyphilis are eliminated, it is not.
6. **The proportion of absolute seroresistance** to effective treatment (two years or more of combined therapy) rises from 11 per cent in early syphilis to 75 per cent in paresis. Latent syphilis rates 33 per cent, meningovascular 46 per cent, late cutaneous 50 per cent, cardiovascular 50 per cent, late visceral, late osseous, late congenital, 60 to 70 per cent (Moore and Padget 1936, and Cooperative Clinical Group)

The residue of seroresistance varies with the type of treatment employed in early syphilis; continuous 11 per cent, intermittent 37 per cent, irregular 68 per cent (Cooperative Clinical Group). Continuous treatment in early syphilis is the great preventive.

8. **Shortening or premature stopping** of the early treatment courses (first four to seven months of treatment) and especially of the arsenical, predisposes to fastness.
9. In the first year neoarsphenamine is less effective than 606, mapharsen not yet evaluated.
10. **Arsenical bismuth therapy** is superior to arsenical-mercury.
11. **Overmassive** or insufficient treatment, after the first year predisposes to seroresistance. Continuous moderate treatment is optimum, prolonged by heavy metal (C. C. G.)
12. **Seroresistance possibly represents** a biologic or metabolic state of the body (see Photinos on pluriglandular therapy, Bernard *et al.* on hypercholesterolemia, 1936) as well as an expression of persistence of the organism (Burke 1940, Kolmer 1936). Hence, in late latency after specific treatment has been carried out to the latency standard, nonspecific methods (ultraviolet light, autohemotherapy, milk injections, rest, iodides) may be considered, but fever is not advised (Stokes, Moore and Padget)
13. **Most observers,** especially European, largely disregard serologic fastness in clinically well persons after adequate treatment in whom examination and observation have failed to show active involvement. (Ravaut, Schulman and Levy, Jadassohn Handbuch, Wile, Scholtz, Spiethoff, Stumpke, Kerl.)
14. **Recall that ultimate reversal** of a seroresistant case to negative does not preclude progression, especially cardiovascular involvement under a cloak of seronegativity, or of progression or revival in nervous system or viscera (liver)
15. Conceding the nonconformity of the clinical material in the literature and the uncertainties introduced by multiple factors in treatment and infection, the seroresistant case may be estimated to have from 35 to 61 per cent prospect of reversal by an additional year of treatment with bismuth, or bismuth and an arsenical, or fever alone. The higher estimates suggest inadequate initial treatment rather than actual seroresistance.

The advances in our knowledge of seroresistance or reagin-fastness within the past decade are summarized in Fig. 210.

It would appear that as in latency in general, the more thoroughgoing the search of a supposed Wassermann fast case, the more likely is some grave

form of syphilis to be uncovered as a collateral or underlying manifestation Nothing therefore, could be more ill advised than casual assurance to Wassermann fast patients that their positive blood tests have no meaning Painstaking investigation suspended judgment, and observation over a long period are therefore indispensable to the interpretation of fixed positive serological tests.

On the other hand, it must be recalled that most material was gathered from sick rather than well population, so to speak, and that it would therefore tend to collect the graver aspects of serological resistance rather than the more benign forms. That this may be an important consideration is suggested by Ravaut comment on Schulmann and Levy discussion of the fixed-positive Wassermann. Waltz, inspired by his chief, Ravaut, made an extended survey of the serological status of elderly veterans at Ivry with respect to the existence of positive serological tests with no other manifestations of the disease. While the figures are apparently not yet published Ravaut believes that the positive Wassermann in old age and the positive Wassermann as such, as manifestation of syphilis in the established infection, should be minimized. He feels that many of these elderly persons could well congratulate themselves that they had not been subjected to treatment test of reversibility which might easily have injured their viscera and left them in worse state by far than that of possessors of mere positive serological tests.

Wassermann-fastness in Latency—The Cooperative Clinical Group with Moore as spokesman finds that once the patient achieves true latency the proportion of patients obtaining "satisfactory" results from treatment is approximately the same whether the patient remains Wassermann-fast or undergoes permanent serological reversal to negative

Reactivation after Treatment.—The paradoxical result of increasing the positiveness and resistance of a serological test by treatment which often clears up other symptoms when present, is not a rare experience. Especially since the inauguration of bismuth has it become not uncommon to see weak positives converted into strong positives which may ultimately subside after a delay of months or even years. In prenatal cases particularly one may observe this reactivation or provocation of a serological test which becomes irreversible. Without any exact figures to offer we have, nonetheless, observed such a reactivation to be the predecessor of interstitial keratitis and are inclined to regard it as a symptom of revival of the infection for which treatment should be thorough and persistent even if ultimate reversal to negative does not ensue. In this connection bismuth "lag" (Chapter VI) should be recalled

German opinion, as expressed in the Handbuch summary and subsequently (1934) as collected by the Dermatologische Wochenschrift, attaches relatively little clinical importance t this state maki g it entirely matter of individual judgment whether or not such patients shall be periodically treated, continuously treated, allowed to marry or t conduct their lives otherwise without reference to their serological status. French opinion, collected in the discussion of Schulmann and Levy paper disclosed majority opinion similar to the German view Schulmann and Levy themselves opposed extended treatment, preferring observation and serological tests at three months intervals with spinal fluid examination once year R vaut tended to minimize the monosymptomatic serological test and to believe that clinical considerations and good sense should settle treatment decisions in all such cases, rather than the outcome of laboratory procedure Pautrier supported the same view Galliot has pointed the question by an account of two treatment disasters which he believed had resulted from attempted yearly and persistent treatment of patient with monosymptomatic Wassermann-fast conditions. Tzanck and coworkers (1934) insist that regular and intensive treatment from the start does way with serologic fastness.

On the other hand, Sézary insisted that resistant serological tests mean visceral syphilis and emphasized the importance of thoroughgoing search. Gougerot distrusts fixed-positive cases and advises against their marriage Louste does not interdict marriage but considers it matter

for individual judgment whether t treat or not. Moutbur emphasized the necessity for great conservatism in permitting the marriage of women with monosymptomatic positive Wassermann reactions, saying that in series of such patients observed in his clinic, not one had been able to give birth t healthy child, in spite of treatment during pregnancy amounting in some cases t as high as 10 Gm. neoarsphenamine. In English-speaking countries, Burke has insisted that no such condition as Wassermann-fastness need exist in effectively treated early syphilis, managed by the alternating continuous scheme. Kolmer believes that fixed-positive serological tests mean active foci and indicate periodic treatment throughout the persistence of the condition, if not through life. Wile in an excellent expression of his views deplores the overtreatment of serological irreversibility believing that much damage is done thereby and that the panic which too often arises physician and patient under such conditions should be controlled by rational considerations. At the same time, progression, especially in the direction of cardiovascular syphilis, under the mask of monosymptomatic seropositive latency must be carefully watched. Seropositive latency in the man is to some extent different problem from that in the woman, for the birth of syphilitic child, even in seronegative latency is form of relapse whose frequency is as yet unknown. With Ravaut, we believe that the consideration of clinical indications and good sense will allow age and time factors to decide the issue of treatment rather than the serological test as such when latent syphilis is recognized in the later years of life.

Treatment *of* Serological (Reagin) Fastness.—Courses which should secure the maximum effectiveness in the prevention of serological fastness in early syphilis are outlined in Chapter XIV Serological fastness of the monosymptomatic type in latency should first be weighed by the criteria and methods applicable to latency in general (p 440) If after an application of these principles, it seems proper to treat or to prolong the treatment of the absolutely monosymptomatic latent case at all, we should say that a six months rest period—followed by not less than three courses of an appropriate bismuth salt and a year of iodide on a two months on two months off schedule—could be regarded as a therapeutic test of the reversibility of the serological reactions as such. This, too, would in a previously untreated monosymptomatic case constitute a treatment for life insurance which in all probability would disturb the immunity balance of the latent patient as little as possible. The use of the arsenicals for this purpose should be given second place and be contingent on very careful consideration of age and time factors and of the question of pregnancy as a possibility In young men and women within the marrying and childbearing age, asymptomatic seropositive latency should as has been said, be treated with something approaching the intensity of early syphilis in the effort to secure a reversal.

If these measures fail, and it is believed necessary to go farther with the matter especially in the younger and more robust patients, various methods in addition to the suggested use of bismuth, now finding current support in the literature and in practice will be found summarized in Fig. 211 Of all the steps mentioned, evaluation, rest period, and change of the mode of attack by changes of drug, either singly or in combination, are the basic essentials.

Bismuth is probably the most effective drug at present available, the results secured by various authors ranging from 34 to 75 per cent reversals with from one to four courses of the drug.

We have had several favorable experiences with boiled milk. It is, we believe a serious question whether fever therapy is justifiable in dealing with monosymptomatic cases except as a sequel of inappropriate or inadequate treatment in young adults. The experience of Kemp and Stokes was favorable (46 6 per cent reversals) so far as immediate results were concerned, using typhoid-paratyphoid vaccine but it should in all cases be followed up by bismuth for relapse is usually prompt

Vigorous repeated ultraviolet irradiation combined with injections of autogenous blood (autohemotherapy) has been successfully employed by Rajka and Radnai since 1929 for the treatment of resistant syphilis, including serologically fast patients and patients with cardiovascular and neurosyphilis. The blood injections were employed for their additional desensitizing effects, as suggested by the experimental work of Pörtök, Lehner and Rajka. On the other hand, Ambrosio found that ultraviolet, roentgen-rays, radium, cobalt, and nickel had influence on the results of the Wassermann test. The observations of Rajka and Radnai were, however in part confirmed by Gottron at the Copenhagen Congress in 1930. Rajka and Radnai emphasize that to be successful the treatment must be intermittent, not more than 30 irradiations in series, and the autogenous blood being drawn half an hour after the treatment and reinjected intragluteally or intracutaneously. The irradiations were given three times a week, and the amount of

Fig. 211

RECOGNIZED METHODS OF TREATING WASSERMANN FAST PATIENTS

1. Preventive
2. Evaluation (complete examination) and expectancy with periodic (usually annual) reexamination and quarterly tests.
3. A rest period. The test may become spontaneously negative in three to twelve months and remain so, especially after bismuth and fever
4. Change of drug. This is probably the most important element in the whole range of possibilities (Burke, Belding, Stokes *et al.*)
5. Rest followed by change of drug (Burke, Tobias)
6. Bismuth—regarded as specially effective by Grund, McCafferty and MacGregor, Belding, Sutton, Levin and Schwartz, Tobias *et al.*, probably an example of (4)
7. Bismuth arsphenamine sulphonate (Kolmer, Stokes, Miller and Beerman).
8. Sodium iodide intravenously (Burke, Vercellino, Beinhauer, Schwartz and Beerman) 1 to 10 Gm. daily 10 per cent solution (intravenously)
9. Sodium thiosulphate (hyposulphite) intravenously 10 to 20 cc. of 20 per cent solution for 12 to 15 injections (Ravaut, Flurin, Beinhauer and Jacob, Werlagick, see Tobias *et al.*) Also with addition of Lugol's solution.
10. Milk injections (5 to 10 cc. milk boiled five minutes) or Aolan once or twice weekly intramuscularly alone or with alternating injections of bismuth (Burke, Greenbaum and Wright, Stokes)
11. Autohemotherapy. Physiotherapy (ultraviolet light)
12. Balneotherapy—sulphur baths, Turkish bath (Burke, Prosser White, Cady and Everhardt)
13. Fever therapy—with sulphur in oil (Schroeder, Flurin), Ducrey vaccine (Gougerot, Sézary *et al.*, Burke), typhoid-paratyphoid vaccine (Kemp and Stokes), malarial therapy
14. Experimental and unevaluated method
    (a) Pluriglandular therapy. Total dosage of various mixtures ranging from 1.2 Gm. of the more active (thyroid) to 12 Gm. of the less active preparations (ovary) by mouth or injection (Michaelides and Kloukinis, Photinos)
    (b) Irradiation of the spleen (Gougerot)
    (c) Cerium compounds (Bertillon)

INDIVIDUALIZE EACH CASE OF WASSERMANN-FASTNESS. IF ENTIRELY ASYMPTOMATIC, OBSERVATION NOT TREATMENT MAY BE THE ONLY NEED

blood withdrawn ranged from 2 to 15 cc. and totalled 20 injections. The positive Wassermann reaction became negative in 50 per cent of cases of latent syphilis in which previous chemotherapy had failed to secure reversal, and in 28 per cent of patients with resistant Wassermann reactions in neurosyphilis. It remained negative for from two to thirty-six months. About 50 per cent of the cases ultimately became positive again. Gottron commended the method as one suitable for employment in patients rendered syphilophobic by their persistent positive serological tests. The constitutional and tonic effects are excellent.

Serological Fastness with Visceral and Other Lesions.—Wassermann-fastness as an expression of visceral, vascular and neurosyphilis becomes, relatively speaking, a secondary matter. The object in all such cases should

be to secure the best possible symptomatic results for the patient, and the type of treatment and drugs employed must be absolutely dependent upon the major symptomatic indications and the rules for treatment of the structures involved rather than on any considerations affecting the positive serological test. It may be expected that approximately 50 per cent of visceral and vascular syphilis will become serologically negative in the course of the appropriate treatment for the condition. The residuum of 25 to 50 per cent should be treated rather by the clinical indications in the case, under expert direction, than by the mere fact of a persistent positive serological test. It would, to our minds, for example, be quite inexcusable to subject cardiovascular syphilis to fever therapy in the effort to secure a negative blood regardless of the general status of the case.

Serologic Fastness Under Intensive (Five-Day to Ten Week) Therapy for Early Syphilis.—The conditions governing intensive therapy result in a gradual decline in seropositiveness after the administration of the indicated amount, as shown by quantitative serologic procedure. Most of the available data are thus far for the five-day to ten-day method. By the fourth month after the initiation of treatment, the patient should be lastingly seronegative and most patients with early syphilis become so by the eighth to twelfth week. Hyman and coworkers (1939) report one case (6 per cent) doubtfully positive after five years Leifer Chargin and Hyman (1941) reported 9 cases of seroresistance in 386 treated with five-day arsenotherapy eight of them in the small dose mapharsen series. According to Elliott, Baehr Shaffer Usher and Lough, the largest series of five-day cases thus far published showed 3 to 20 per cent seropositive after 6 to 12 months, depending on the stage at which treatment was begun. If the titer of reagin rises sharply after a period of decline, a relapse has occurred and the patient is retreated. Adequate information on latency and so forth is not yet available.

"Cure" and Arrest in Serological Fastness.—Serologically fixed positive cases are subject to the same rules with reference to the interpretation of cure and arrest as are all latent cases. They should not be dismissed from observation throughout life. Treatment, especially with the arsphenamines, once begun should be carried through a heavy-metal phase to avoid reactivation of the infection. The widest differences of opinion may justly exist on the advisability of maintaining a state of latency by periodic treatment, and the field of speculation is easily wide enough to embrace the almost diametrically opposite opinions already reviewed.

GENERAL HYGIENE OF SYPHILIS

The first step in a general hygiene of syphilis is the complete establishment, so far as possible of rapport between physician and patient and the adequate instruction of the latter at the very first interview in regard to the general nature of the disease, the problems which treatment will inevitably raise and the course which the patient should pursue to protect his lif and his associates to the greatest possible degree from unfavorable consequences of his infection. After the diagnosis is conclusively established, the necessary time should be taken to lay before the patient the points outlined in Fig 212. At no time in the life history of the disease or of the patient is he so open to impressions, to intelligent influence and to a frank, dispassionate statement of the facts. The term "first interview" must not be too literally interpreted

Vigorous repeated ultraviolet irradiation combined with injections of autogenous blood (autohemotherapy) has been successfully employed by Rajka and Radnai since 1928 for the treatment of resistant syphilis, including serologically fast patients and patients with cardiovascular and neurosyphilis. The blood injections were employed for their additional desensitizing effects, as suggested by the experimental work of Pertik, Lehner and Rajka. On the other hand, Ambrojio found that ultraviolet, roentgen-rays, radium, cobalt, and nickel had influence on the results of the Wassermann test. The observations of Rajka and Radnai were, however, in part confirmed by Gottron at the Copenhagen Congress in 1930. Rajka and Radnai emphasize that to be successful the treatment must be intermittent, not more than 30 irradiations in a series, and the autogenous blood being drawn half an hour after the treatment and reinjected intragluteally or intracutaneously. The irradiations were given three times a week, and the amount of

INDIVIDUALIZE EACH CASE OF WASSERMANN FASTNESS. IF ENTIRELY ASYMPTOMATIC, OBSERVATION NOT TREATMENT MAY BE THE ONLY NEED

blood withdrawn ranged from 2 to 15 cc. and totalled 20 injections. The positive Wassermann reaction became negative in 80 per cent of cases of latent syphilis in which previous chemotherapy had failed to secure reversal, and in 28 per cent of patients with resistant Wassermann reactions in neurosyphilis. It remained negative for from two to thirty-six months. About 30 per cent of the cases ultimately became positive again. Gottron commended the method as one suitable for employment in patients rendered syphilophobic by their persistent positive serological tests. The constitutional and tonic effects are excellent.

Serological Fastness with Visceral and Other Lesions.—Wassermann fastness as an expression of visceral, vascular and neurosyphilis becomes, relatively speaking, a secondary matter. The object in all such cases should

nation by the physician himself. Such leaflets are best used to supplement viva voce instruction, and for this purpose we have often had intelligent patients read the sections on the control of infectiousness and personal hygiene in our own text. A lay substitute for the physician, as for example, social worker may give the instruction, but this method think is inferior both in its influence on the patient and on the rapport between physician and patient which proper technic of presentation usually establishes. The method, none the less, can be made effective in clinics by competent social service chief and organization.

Diet, T bacco Alcohol.—Diet, being regulated to no small degree by the prevention of reaction, is discussed on page 869 The use of tobacco, formerly interdicted for many years, has lost much of its significance for relapse and recurrence with the institution of modern treatment. Like advice on sex matters, honoring in the breach rather than the observance is to be expected today and if the patient pursues treatment consistently little attention need be paid t the matter The chewing of tobacco is more deleterious than the smoking from the standpoint of exciting local lesions, and positive danger in the later years of the disease lies in the development of leukoplakia.

While the occasional case may require touch of horrific management, patients with late syphilis of nondefections type should not be made the victims of needlessly ascetic régime. Alcohol has been discussed as provoker of complications, but there are many other reasons which we believe more or less inevitably make the syphilologist, who views his problem broadly an antagonist of the liquor traffic (*pace facta*, regardless of his reaction toward Constitutional prohibition as such. The general effect of the use of alcohol varies through the widest possible range in different individuals, so far as their syphilitic infection is concerned. One sees on the one hand persons of the most exemplary even abstemious make-up, carried away by the worst complications *of the disease, and on the other born convivialists and gone-the-ropes sots, escaping with* comparatively benign syphilitic infections. The weight of tradition is against permitting patients with syphilis t use alcoholics, and with this tradition our experience is, in the main, in accord.

Sex Hygiene of the Syphilitic Patient.—In matters of sex hygiene the physician may advise—in his professional capacity he too often proposes but the patient disposes—the exercise of continence throughout the infectious years of the disease. The bearings of this problem on marriage in particular are more fully discussed under syphilis and marriage, page 1069 Where it is expected and in fact, where it is not expected that the patient will be amenable, it is the duty of the physician to warn specifically against all forms of intimate contact to instruct the patient, if the sumptuary laws too generally on the statute books permit, with regard to the mechanical protection of himself and *his partner in sexual intercourse. The most shocking and disastrous* denouements have followed a mistaken adherence to serological criteria of infectiousness, the seronegative patient either taking the law into his own hands or being permitted by his physician to have unprotected intercourse once his Wassermann became negative. The principles on this matter should be carefully reviewed (p 166)

The effect of irritation from excessive sexual intercourse in women in promoting the development of infectious genital lesions is well known. Cleanliness, surface disinfection, and reduced activity are therefore proper management. There is, however no other evidence that the living of the ordinary normal sexual lif materially affects the course of syphilis in one way or another. The excessive sexual activities of the paretic patient may underlie family crises and contribute somewhat by exhaustion, perhaps, to the deteriorative process. Similarly the impotence of late neurosyphilis may give rise to troublesome situations and may often be quite as much psychological as organic. Certain forms of treatment, such as tryparsamide, *are reported by patients to have* directly stimulative effect on sexual activity and priapism and jaculatory disturbances may accompany lower-cord irritation or follow intraspinal therapy Patients who are undergoing sexual revivals under the tonic effect of treatment should be warned to stay within bounds. The fear factors, particularly in the case of an uninfected partner may be seriously disturbing to normal sexual function.

The Importance of Rest.—Rest is one of the potent and often life-saving factors in the general management of the syphilitic patient.

In a disease such as syphilis, involving wide ramifications throughout the patient's physical and mental life rest must include more than mere sleep important though this is. Reduction of irritation and overstrain contributes greatly at times to the favorable progress of a syphilitic infection, especially if there is an involvement of the nervous system. Eight hours sleep a night, two of them before midnight temporary relief from business pressure by an out-of town trip the breaking of a prolonged treatment siege by judicious rest periods and lazy vacations à la Izaak Walton, have marked therapeutic worth. The practice of breaking the day in the middle by half an hour of complete relaxation lying down with a short nap is life-saving in many patients in the middle and late forties or fifties even if there be no active disease of the cardiovascular system to compel it. Rest in bed is of value in patients with greatly reduced physical reserve or local lesions, if they are kept irritated by movement or hypostatic congestion. The occasional undoubted value of a "milk cure with its weeks of rest in bed and forced feeding with gain in weight is by no means to be despised. Routine sedation, especially with barbiturates and bromides is to be discouraged psychotherapy encouraged.

Locus Minoris Resistentiae.—The patient should be instructed and managed with respect to the weakest part of his organization, always the favorite site of attack by a syphilitic infection. The liver and nervous system of the alcoholic, the cardiovascular and particularly the coronary mechanism of the hard-pressed business man and physician, the brain of the intellectual worker the ankles and knees of the tabetic, the bones and skeletal tissues of the laborer and the person subject to physical accident must all be borne in mind for protection against injury and overload, lest their weakest spots become the sites of syphilitic lesions.

The Mental State of the Syphilitic Patient.—Regimen undoubtedly has its good effects, and the emphasis thus far given to a disciplined management of the disease may perhaps have overstated them. The physician should however avoid the tendency to surround his patient with petty restrictive prohibitions or to create an atmosphere of therapeutic asceticism On the other hand, some patients, in their eagerness to cooperate, demand precise and multiplied instructions, and these should be gently persuaded away from their penchant for regulation.

Syphilophobia.—The phobic mentality finds one of its most distressing fields of activity among syphilitic patients. Syphilophobia is less a product of syphilis than an evidence of a constitutional trend of mind which leans toward hypochondriasis in one direction or another Most of these patients are markedly vagotonic, subject to vasomotor crises, and sometimes literally psychotic though not necessarily as a result of their syphilitic infection A careful appraisal of the situation will sometimes show the syphilophobia to be merely a fixation expressive of some deeper-lying complex situation in the patient's mental life When this is the case, no amount of argument or persuasion seems capable of correcting the situation without, perhaps, neuropsychiatric intervention. On the other hand, the average syphilophobe terrorized by hearsay or unfortunate contacts with the literature of the subject, can be not infrequently completely disabused of his notions by thoroughgoing authoritative consultation. In dealing with such patients the consultant must not for a moment allow his presuppositions and instinctive diagnosis to dominate his approach to the case He must conduct the most thoroughgoing examination and, in fact insist on the carrying through of every procedure which will resolve a doubt to say nothing of creating a conviction in the patient that no

stone has been left unturned. Thus managed, with the full armament of syphilological investigation discharged against the patient's fears, the most remarkable and satisfying restoration to confidence and activity takes place both in patients who have and who do not have the disease.

Apart, however from the distinctly phobic group of mental and nervous disturbances, the successful management of the day-to-day mental problems of the "normal" syphilitic patient calls for both a deep and a broad humanity In no disease does the ministry of the physician perform a more needed service, or achieve more gratifying responses. It is precisely in the patients whom one most desires to help that the opportunity for human as distinguished from purely professional service comes. The mental state of the finer types of patients with this disease still reflects the stigmatization which has so long marked the superficial and unthinking world attitude toward sexual problems. Some of them are, of course, painfully almost repellently persistent in their reiteration of the disgracefulness of their situation and their surroundings. For such patients, immutable in their sackcloth and ashes, little can be done. On the other hand, a large proportion of patients are readily responsive and deeply appreciative of the help of the physician in reorienting themselves toward their situation and recovering their self-respect. They make not only mental but surprising physical responses, which are entirely unattainable until the root of the situation has been touched

The idea that he is lost, that foul and gross decay waits him, that he can never marry that insanity is certain, that his wife, if he has one, will disown him, is tragically real to many patient. The time and patience spent in explaining way and correcting these mistaken notions are part of the actual treatment of the disease. In dealing with such patients, we quot them figures as exactly as we can and illustrate with parallel cases outside the range of the patient acquaintance. W invite the patient on the service to look about him and note the wrecks who come in and restored men and women who go out. Nearly always, in his search, the hope that is instinctive, leads the patient to find someone worse situated than himself who has recovered, and his own return to confidence ensues. This is one of the great advantages of managing syphilis in the aggregate—"there none so worse but there worser.

Anxiety Neuroses.—True anxiety complexes are not uncommon in syphilis and must be painstakingly unraveled and set right with psychiatric assistance if necessary The patient who shows a persistent depression or failure to respond is not always suffering from a syphilitic cerebral process, although cortical vascular degenerations do produce deceptive imitations of anxiety neuroses. When the trouble is finally unearthed we find it wise to be systematically encouraging to anxious patients, although without sacrifice of the ultimate truth if in the end it must be told. It is not, of course wise or necessary to throw all prognostic caution to the winds, and he who does so has only to travel a short distance before the facts overtake him and end his prestige. But the value of an honestly hopeful but clear and conservative statement to the patient cannot be overestimated.

Family Problems—the Tradition of Secrecy—The question as to whether or not the patient—often the innocently infected member of the family—shall be informed as to the diagnosis has many aspects. Undoubtedly occasions arise in which damage may be done by informing an introspective and phobic individual or one deeply imbued with the moralistic conceptions of syphilis as a punishment for vice, of the fact that he or she has the disease. On the other hand it is extremely difficult to secure cooperation from a patient not informed as to the situation and particularly is this so when an intensive form

In a disease such as syphilis, involving wide ramifications throughout the patient's physical and mental life rest must include more than mere sleep important though this is. Reduction of irritation and overstrain contributes greatly at times to the favorable progress of a syphilitic infection, especially if there is an involvement of the nervous system. Eight hours sleep a night, two of them before midnight temporary relief from business pressure by an out-of town trip the breaking of a prolonged treatment siege by judicious rest periods and lazy vacations à la Izaak Walton have marked therapeutic worth. The practice of breaking the day in the middle by half an hour of complete relaxation lying down, with a short nap is life-saving in many patients in the middle and late forties or fifties even if there be no active disease of the cardiovascular system to compel it. Rest in bed is of value in patients with greatly reduced physical reserve or local lesions if they are kept irritated by movement or hypostatic congestion. The occasional undoubted value of a "milk cure with its weeks of rest in bed and forced feeding with gain in weight is by no means to be despised. Routine sedation, especially with barbiturates and bromides is to be discouraged psychotherapy encouraged

Locus Minoris Resistentiae.—The patient should be instructed and managed with respect to the weakest part of his organization, always the f vorite site of attack by syphilitic infection. The liver and nervous system of the alcoholic, the cardiovascular and particularly the coronary mechanism of the hard-pressed business man and physician, the brain of the intellectual worker the ankles and knees of the tabetic, the bones and skeletal tissues of the laborer and the person subject to physical ccident must all be borne in mind for protection against injury and overload, lest their weakest spots become the sites of syphilitic lesions.

The Mental State of the Syphilitic Patient.—Regimen undoubtedly has its good effects, and the emphasis thus far given to a disciplined management of the disease may perhaps have overstated them The physician should however avoid the tendency to surround his patient with petty restrictive prohibitions or to create an atmosphere of therapeutic asceticism. On the other hand, some patients, in their eagerness to cooperate, demand precise and multiplied instructions and these should be gently persuaded away from their penchant for regulation.

Syphilophobia.—The phobic mentality finds one of its most distressing fields of activity among syphilitic patients. Syphilophobia is less a product of syphilis than an evidence of a constitutional trend of mind which leans toward hypochondriasis in one direction or another Most of these patients are markedly vagotonic subject to vasomotor crises, and sometimes literally psychotic though not necessarily as a result of their syphilitic infection. A careful appraisal of the situation will sometimes show the syphilophobia to be merely a fixation expressive of some deeper-lying complex situation in the patient's mental life When this is the case, no amount of argument or persuasion seems capable of correcting the situation without, perhaps, neuropsychiatric intervention. On the other hand the average syphilophobe, terrorized by hearsay or unfortunate contacts with the literature of the subject, can be not infrequently completely disabused of his notions by thoroughgoing authoritative consultation. In dealing with such patients the consultant must not for a moment allow his presuppositions and instinctive diagnosis to dominate his approach to the case. He must conduct the most thoroughgoing examination and in fact, insist on the carrying through of every procedure which will resolve a doubt, to say nothing of creating a conviction in the patient that no

gation, may have a catastrophe of the first magnitude on his hands. It was the occurrence of situations such as this which led the Mayo Clinic to adopt a standing rule that none should communicate the diagnosis of syphilis to the patient except the Syphilologic Section, which could do so after a full investigation of its authenticity

SYPHILIS AND INTERCURRENT DISEASE

Syphilis is so often detected in the course of examination for other ailments and without any special or apparent relation to the patient's chief complaint, that special consideration should be given to certain interrelations and to the treatment appropriate to the circumstances.

Syphilis and Diabetes.—Unquestionably from the literature, the published experience of experts in diabetes, the examination of diabetics with concomitant syphilis, and the experience of syphilologists, diabetes due to syphilis, if it exists at all, is a rarity Diabetes in persons with syphilis which responds curatively to treatment for syphilis is likewise a rarity· so great a rarity in fact, that the huge experience of Joslin and his coworkers cannot record a convincing case. Diabetes is clearly therefore not a parasyphilitic disease as some overenthusiastic proponents in the first several decades of the eighty-year-old discussion were inclined to suggest. It is possible that a syphilitic who becomes diabetic has become so because of his syphilis, though far more probably independently of it. The broadening conception of the causal glycometabolic mechanisms involved permits the belief substantiated by occasional cases, that syphilis of the nervous system may have a diabetic accompaniment or consequence as well as syphilis of the pancreas. The incidence of syphilis in diabetics is, by the criteria used approximately that in the population at large the relations of the disease to the known causes of diabetes mellitus probably minimal and insignificant. In general, the diabetic with syphilis, laboring as he does under a double disadvantage, should, first of all, be proved a diabetic by rigid test criteria, and then should have his diabetes dealt with independently of the fact that he has syphilis. To what extent coexistent syphilis aggravates diabetes is not clearly known though there are speculations relative to the roles of arterial injury and the general effects of infection on diabetics which lead to the belief that syphilis aggravates diabetes. In therapeutic tests to determine the importance of the syphilitic factor if such exists, in a given diabetic case, occasional striking improvements in glycosuria, and even its occasional complete disappearance under antisyphilitic treatment, have been observed. This, it must be admitted, does not establish beyond question, the syphilitic origin of the diabetes. Elmer and Kedzierski, and most recently Joslin, McDaniel and Marks, have emphasized that the mere disappearance of glycosuria does not establish the cure of diabetes but that restoration of blood sugar and carbohydrate tolerance to normal and a raising of the renal threshold of sugar elimination are all necessary parts of the demonstration of a causal relationship when an apparent diabetic recovers under treatment for syphilis. In only six of 258 cases studied by the last mentioned authors could an even plausible case for the true syphilitic origin of the diabetes be made out, when such criteria were applied, and they and Williams and Kitchell likewise have emphasized the conclusion that prolonged observation after the improvement of the glycosuria does not tend to indicate that the "cure" of the diabetes is actually established. Generally

speaking then, a syphilitic with diabetes should be treated for his diabetes by the most modern criteria and methods. His tolerance of antisyphilitic treatment under these conditions is, according both to our experience and that of Moore satisfactory Therapeutic test results cannot be accepted on their immediate face, but must be evaluated after prolonged observation by those competent to study the diabetes as such

The literature of the syphilis-diabetes question is bumpy with controversy and occasional polemicism. Probably the ablest summary completely covering the early literature was that of Lemann in 1929 Warthin and Wilson precipitated an angry reaction against their often misquoted and over-emphasized statement that changes produced by syphilis in the pancreas might make it an important factor in pancreatic diabetes. It is only fair to say that uncritical examination of the diabetic side of the question has been matched by equally uncritical examination of the syphilitic side on the part of students of diabetes. The revolution now occurring in serologic diagnosis of syphilis will probably considerably modify our conceptions of syphilis as an intercurrent disease but certainly something more than a single and not infrequently hypersensitive serologic test on the blood or "history of infection must be offered as an adequate evaluation of the syphilis recognized in diabetic individuals. Until such evaluation is complete with large autopsy material t back it, syphilis-diabetes relationship will remain a field for opinion rather than for proved fact, and one can base his opinion on choice of views gained from yet incompletely evaluated material. The trend of opinion is as above described.

Some hesitation in the use of bismuth in the treatment of syphilitics with diabetes is developing from the observations of Epstein; Corson, Decker and Williams (1940) and Peters (1942) of the Johns Hopkins Clinic that bismuth, like lead, may be mobilized in the circulation with increased risk of toxic effects under conditions of acidosis. Such an observation would seem only to point t the necessity for placing the diabetic with actual or threatened acidosis under a properly regulated diet and insulin therapy before beginning intensive administration of heavy metal

Syphilis and Tuberculosis.—The interrelations of syphilis and tuberculosis present a picture of confusion and opinionation slowly resolving itself into definitive and valid principles in much the same fashion as is taking place in the diabetic field. Much the same criticisms of the available material in the literature apply to both problems. Tuberculosis is evaluated and treated by experts in tuberculosis, while syphilologists have a relatively small hand either in the diagnosis or in the selection of therapy on syphilologic principles. The coincidence of syphilis and tuberculosis offers many opportunities for diagnostic confusion, as pointed out by Padget and Moore (1936) There are striking diagnostic resemblances in the histopathology of the two diseases autopsy evaluation leads more easily to a recognition of tuberculosis than of syphilis up to and including late latency and late syphilis itself In the field of pulmonary tuberculosis versus pulmonary syphilis, the majority of observers are agreed that differentiation is impossible except in congenital syphilis, other than by exclusion. Syphilis is known to exert accelerating or unfavorable effects on the outcome of other forms of pulmonary disease as for example in delayed resolution of pneumonias. Relatively seldom is an adequate search for both diseases conducted at the same time in the same person. According to Goldblatt (1939) this may result in the overlooking of one-half of the tuberculosis in the tuberculous individuals, and one-seventh of the syphilis in the syphilitic individuals. Serologic tests for syphilis, almost the sole criterion of diagnosis of the disease in many of the older series, have a definite margin of nonspecificity (about 8 per cent, Parran and Emerson, 1939) with the increasing knowledge of the incertitudes of the positive serologic reaction, it is possible that the margin of error in the diagnosis of syphilis in tuberculous individuals by serology alone will become larger rather than smaller thus diminishing still further the conclusiveness of the old literature on both diagnosis

and treatment. The nonspecific effects of treatment for syphilis, particularly with the arsphenamines, on tuberculous processes (Chapter V) interfere materially with therapeutic test interpretation. While this type of interpretation has not as yet proved to be of importance in pulmonary tuberculosis, its actual significance is unknown. It would appear therefore that the foundation for exact evaluation of the influence of syphilis on tuberculosis and of treatment for syphilis on both diseases, when simultaneously or successively present, does not as yet exist.

The more recent literature, despite evidently increased attention to these considerations, still contains flat contradictions difficult to explain. Padget and Moore (1930) utilizing their own and Turner's experience with Johns Hopkins material, conclude that the coincidence of tuberculosis and syphilis seems less frequent than expectancy under the laws of chance whereas Goldblatt (1939) in an even larger material, concluded that syphilis appeared to have a predisposing influence on tuberculosis which became particularly manifest in the older age groups. Their material indicated that there was more tuberculosis per thousand patients with prior syphilis than per thousand without prior syphilis. Rather tending to support the belief that tuberculosis is either more prevalent or more serious or both in individuals who have had syphilis, are Hall's actuarial figures frequently cited in which the mortality of a group of persons thoroughly treated for syphilis was notably higher (147 per cent) than in nonsyphilitic individuals pulmonary tuberculosis, pneumonia and cancer being the outstanding causes of the higher mortality

Current figures for the coincidence of the two diseases range from Turner (1930) (Johns Hopkins syphilitic out-patients) 1 0 per cent and Trail (1939) (British experience) 1 42 per cent, to 3 6 per cent Goldblatt (1939) (Shoemaker Clinic, Cincinnati) 4 per cent Warring (1939) (Laurel Heights Sanitarium Connecticut) and 3.5 per cent, Berg (1937–39) (Seaview Sanitarium Staten Island) Berg, separating Negroes and whites, found 4.5 per cent for the former 2.5 per cent for the latter The Negro figure is notably higher in other estimates including the National Tuberculosis Association survey of 4 1 per cent white and 21 per cent Negroes. Murphy and Bromberg (1941) obtained closely comparable figures of 5 4 per cent white and 17 4 per cent Negroes.

The combination of syphilis and tuberculosis requires more thorough going analysis on the basis of the age and type of both infections. Most of the large-scale statistical material deals with pulmonary tuberculosis, in which classification is on the basis of the NTA formula of far advanced moderately advanced minimal and extrapulmonary while the classification of the syphilis, when not serologic and over-burdened with doubtful reactions, is largely that of late syphilitic manifestations (Warring for example) ranging from late congenital to neurosyphilis, with an enormous preponderance of late latency It would seem therefore that most of the material to date, while it may have high individual significance, has thrown relatively little light on the serious public health problem of the person with active tuberculosis who simultaneously presents active and infectious syphilis. Padget and Moore's (1936) criticism of the tendency to consider tuberculosis the more important of the patient's ailments, is well taken, and justifies their insistence that both diagnosis and treatment should be individualized, supervised and conducted by experts as Joslin and his coworkers have pointed out for diabetes. The problem of how to manage early syphilis in the presence of early pulmonary tuberculosis assumes increasing importance because of the current use of

collapse therapy which maintains an infective or potentially infective syphilis in active circulation, so to speak. There is therefore particular need to study the influence of early syphilis upon tuberculosis acquired simultaneously or immediately subsequent to the syphilitic infection, and vice versa, and the influence of intensive treatment for syphilis upon the progress of tuberculosis especially in its earlier and more active, as distinguished from its fibroid, status.

On this question, the invocation of animal experimental technics has been emphasized by Padget and Moore with concessions as to the unsatisfactory state of the evidence thus far. Ohsawa (1922) whose conclusions have been mentioned previously has observed that rabbits previously infected with tuberculosis have a general increase in resistance to syphilis, and that testicular tuberculosis in syphilitic rabbits progresses more rapidly than in controls. A much more penetrating study of the question by Aronson and Menasse (1938, 1940) based upon the pathologic histology in the experimentally inoculated rabbit, indicates that in the syphilitic rabbit the local inflammatory reaction following the injection of tubercle bacilli into the skin is more intense in character, has more distinctly vascular and hence more extensive distribution, and the tuberculous lesions resemble in their histologic characteristics the primary and secondary lesions of syphilis rather than the characteristic lesions of tuberculosis, even though *Treponema pallidum* cannot be identified by darkfield. Their observations suggest that the subsequently induced (by inoculation) tuberculosis excites the so-called anamnestic reaction in which the second infection, in addition to provoking an antibody reaction against tuberculosis, also provokes antibodies (or reaction mechanism) against the initial infection (syphilis). It would thus seem that under certain circumstances both provocation of the infection and an actual contribution to its conquest by the body can be made by the second or subsequent infection, at least when that second infection is tuberculosis. Much more extensive work, however is still required for the substantiating of such conclusions and all such studies must be subject to the notable differences between syphilis and tuberculosis both in the rabbit and in man.

The general conclusion supported by the observations of Norris and Landis (1933) Gallant (1929) and others, that syphilis unfavorably affects the course of tuberculosis can be set over against the views of Schlesinger (1926, 1932) which have markedly influenced the technic of treatment, to the effect that active tuberculosis seems to modify in a favorable direction the course of the syphilitic infection. Some of the irreconcilabilities will probably be resolved by the point of view emphasized by Padget and Moore (1936) that mass statements on these matters are untrustworthy and that the status of infection in the individual, and the individual's type or degree of reaction to it, as evaluated by experts, would probably furnish the only safe basis for a rational therapy. This has been in the main our own view of the problem. Nicolas and his coworkers, as previously cited pointed out very clearly as regards the nonspecific effect of the arsphenamines on tuberculous processes, that their influence is dependent upon the individual's reaction to the tuberculous infection at the time treatment was instituted. If resistance to the tuberculous process was good or on the increase, treatment effect from the arsphenamines was satisfactory whereas if the tuberculosis was progressing unfavorably the same arsphenamine therapy hastened the decline.

The Treatment of Syphilis Complicating Tuberculosis.—Schlesinger's rules, which seem quite largely to have dominated American practice, adopt four classifications as follows

1. Late syphilis, nonprogressive clinically complicated by recent pulmonary tuberculosis, in which the tuberculous process takes precedence and antisyphilitic treatment is delayed until the tuberculosis lesion has been stationary for several months. Arsphenamines and iodides are avoided.
2. Untreated late syphilis with old fibroid pulmonary tuberculosis in which

arsphenamine may be used in small doses but the risks of fever therapy are unjustifiable, unless paresis is imminent or the tuberculous lesions wholly insignificant.

3. Old stationary pulmonary tuberculosis with early syphilis, in which, if fibroid, the arsphenamines may be used, but cautiously if cavitation is present, watching for signs of progression of the lung lesions. Here Schlesinger lays down the principle, still a matter of controversy though supported by numerous case observations including especially those of Padget and Moore, that the arsphenamines (and particularly 606) can produce grave reactivation with hemoptysis and dissemination of pulmonary tuberculosis.

4. Early syphilis with recent tuberculosis, the most unfavorable combination of all, in which, if the syphilis is not overwhelmingly endangering the patient, antisyphilitic treatment should be limited to the heavy metals, until the tuberculosis is completely controlled.

These basic rules, while in the main supported by current experience, are subject to some important modifications. First, from the experimental side Aronson and Meranze concluded that local experimental tuberculosis pursues an identical course in untreated syphilitic rabbits and in syphilitic rabbits treated with treponemicidal doses of arsphenamine. McDermott, Webster and McCrae (1941) in treating two control series of tuberculous rabbits, one syphilitic and one nonsyphilitic, found that arsphenamine failed to produce demonstrable ill effects on the tuberculosis and that roentgen-ray shadows present in the majority of tuberculous animals almost totally disappeared during the course of treatment in both treated animals and controls.

To the clinical evidence favoring more thorough-going treatment for syphilis than the disease is usually accorded in tuberculous patients, Berg's large series (1927–1939) appears illuminating. In 372 patients, active treatment of syphilis by arsenical injection exerted little or no influence in activating a latent or quiescent tuberculous lesion. Antisyphilitic treatment with arsenicals in submaximal doses did not affect adversely the course of active pulmonary tuberculosis except in terminal cases. The coexistence of syphilis, whether treated or untreated, with pulmonary tuberculosis, did not conduce to a more rapidly fatal course. Exudative lesions in the lungs apparently resolve more frequently in patients treated with arsenicals for coexisting syphilis than in patients not treated. The sputum of patients who were treated with pneumothorax became negative more often when arsenicals were administered for coexisting syphilis than when not so treated. Neither syphilis nor arsenical injections affected adversely the progress of therapeutic collapse therapy. Syphilis, treated or untreated, did not interfere with the healing of thoracoplastic wounds. Hydrothorax, following pneumothorax, occurred slightly more often in patients receiving arsenical injections for syphilis than in those not receiving arsenicals. There was no evidence that chronic or latent syphilis favored fibrotic changes or that the administration of arsenicals or heavy metals interfered with fibrosis. The bacillary content of the sputum impressed Berg as being as good a criterion in judging the status of pulmonary lesions in syphilitic patients as in nonsyphilitic individuals.

Even on the disputed question of the effect of iodide traditionally withheld in tuberculosis because of the widely accepted though incompletely supported view that it promotes the softening and resolution of fibrous tissue and hence interferes with the encapsulation of tuberculous foci, Berg's experience was radical. The administration of large doses of potassium iodide (in one case)

did not inhibit the favorable progress of tuberculous exudative lung lesions and calcified nodules in the bronchial nodes and lung parenchyma.

Warring, with a series of 106 patients (1939) found that the course of syphilis in patients with tuberculosis did not differ materially from the course of the disease in the nontuberculous He adopted four rules, taking account of various factors in both diseases, which may be quoted as follows

1 If the syphilitic disease is in an infectious stage treat it to the point of noninfectivity no matter what the extent or type of the tuberculosis.

2 Should the syphilis be in the latent stage, attention should be paid first to the age of the patient. Patients over sixty can usually be safely allowed to forego antisyphilitic treatment. If the patient is younger evaluate the pulmonary disease. Do not treat patients with far-advanced progressing tuberculosis who appear to have a hopeless prognosis If the far-advanced disease later shows definite evidence of improvement, antisyphilitic treatment can be started cautiously Delay treatment in patients with acute active or exudative types of tuberculosis no matter how small the extent of the tuberculosis. Treat patients with previously active pulmonary disease as soon as it becomes quiescent.

3 In patients with certain early manifestations of active late syphilis (aortitis aneurysm central nervous system syphilis) treat the syphilis if it is felt the patient s life may sooner be endangered by syphilitic infection than by his chronic pulmonary tuberculosis Whereas treatment of syphilis can be delayed in the latent syphilitics while the progress of the tuberculosis is observed it should be begun at the earliest possible moment in patients with active late syphilis

4 Suspend treatment of syphilis if the patient has febrile reactions, hemoptyses develops wet pleurisy or shows, by x rays spread of tuberculosis.

These two groups of observations with the rules deducible from them express in the main the most recent opinions as to the treatment of conjoint syphilis and tuberculosis As reviewers of the problem we would tend to emphasize first the importance of considering the public health aspects of the patient combining active infectious syphilis with any stage of tuberculosis equally with any patient presenting active tuberculosis coincidently with syphilis. The current use of ambulatory methods greatly increases the danger of the distribution of both infections through the community if adequate case-finding and case-holding procedure (follow up) is not employed and early control of infectiousness in syphilis practiced. It would seem therefore that early infectious syphilis, if it is judged unwise to treat it with the arsenicals, should be controlled by sanitarium care.

The improvement in arsenotherapy of syphilis introduced by mapharsen and the arsenoxides makes it safer to use them than was previously the case with the arsphenamines Padget and Moore s (1936) group of unfavorable cases for example may be in part attributable (aside from their conceded influence of coincidence) by their use of 606 the most "pneumotropic" of all the arsenicals (see Chapter VII) The experience of Astrachan and Wise (1938) Warring (1939) and Murphy and Bromberg (1941) with mapharsen has confirmed the reasonable expectation that it would be a materially less reaction-producing and safer drug in the treatment of syphilis in combination with tuberculosis than the arsphenamines. The remaining rules above cited are part of the general principles of syphilotherapy—to treat the more threatening ailment first, and with the greater emphasis to employ caution in preventing therapeutic

shock and paradox where the syphilis is active or of a late focal type in important structures and to employ bismuth which appears thus far to be devoid of unfavorable effect, where there is reason to fear the more rapid action of an arsenical. Our own experience tends to indicate that one of the safest guides to caution in therapy is fever and that the febrile tuberculous patient who is progressing unfavorably will probably respond unfavorably if not disastrously to vigorous treatment for his syphilis particularly with an arsphenamine. With respect to fever therapy there is agreement (Schlesinger Padget and Moore ourselves) that it is dangerous and may reactivate any type of tuberculous lesion, no matter how completely quiescent it may appear to be on clinical examination.

The foreshortened intensive (five-day to twelve-week) systems for the treatment of early syphilis (see Chapter XIV) should not, with our present knowledge, be employed in the treatment of clinically tuberculous individuals

The use of iodide in tuberculous subjects is a controversial topic in which their avoidance is the more conservative course In therapeutic tests, the nonspecific effects of the arsphenamines on tuberculous processes must constantly be borne in mind, and heavy-metal therapy if necessary with mercury (soluble salt intramuscularly) may need at times to be invoked for a decision Even under these circumstances the effect is not absolutely specific (see Fig 499)

Syphilis and Malaria.—The coexistence of these two diseases and the use of malaria in treatment create an important problem All of the heavy metals with the addition of antimony and gold had, according to Cole and coworkers (1940) been shown to influence the behavior of malaria induced or otherwise. Goldman (1938) Cleveland and Turvey (1939) Young and McLendon (1939) Solomon Epstein and Berk (1033) Whitehead and Dorey (1941) and many other observers have testified to the effects of the arsenicals on malaria. Whitehead and Dorey and Goldman specifically even rated mapharsen as far more effective than quinine in quartan infections, and notably more effective than arsphenamine and neoarsphenamine. He employed mapharsen for the termination of tertian malaria in place of quinine. Young and McLendon in examining these statements, took pains to control their use of arsenoxide and tryparsamide for the termination of quartan malaria by reexamination of blood smears as long as twenty-two weeks after the completion of the mapharsen course and found all their patients had become asymptomatic malarial carriers Three of their quartan malaria patients who received tryparsamide, examined one year after the completion of tryparsamide treatment still showed *P malariae* in the bloodstream It is apparent therefore that where syphilis and malaria coexist, the arsenicals cannot be relied on to terminate the malaria. The action of bismuth in the control of malaria coincident with syphilis has been discussed in Chapter VIII and in connection with malarial therapy The effects of the thio-glycolate suggested by Schwartz (1939) on the malaria, seems to be the most pronounced. Winckel (1941) from a large experience emphasizes that neoarsphenamine may modify the behavior of a malaria and render it asymptomatic without ridding the blood of plasmodia. It cannot be used to replace quinine for therapeutic effect. It would appear therefore that where the coexistence of the two infections is demonstrated or suspected quinine must be employed to evaluate and eliminate the malarial factor

Syphilis and Febrile Disease.—Fever is a not uncommon symptom of syphilis in all stages and the disease unquestionably acts to prolong the febrile

phase of acute and chronic infections though it does not necessarily contribute to the elevation of the temperature. McLester has noted this in typhoid fever it is a well-known occurrence in the postcritical persistence of fever after pulmonary infections occasionally modifies the temperature curve of malaria and may influence the behavior of chronic sinus infection. Intercurrent syphilis in malignancy especially of the liver may be obscured in diagnosis by a low persistent fever which responds to treatment for syphilis giving the impression of a false therapeutic test.

Syphilis and Septic (Streptococcal) Infection.—Since the occurrence of apparently false positive serologic reactions in subacute bacterial endocarditis is now reasonably established, therapeutic confusion may arise from the influence of treatment for syphilis in the presence of this and other forms of septic infection Le Cocq (1936) reported on the usefulness of neoarsphenamine in serious staphylococcic infections.

Experimental studies by Osgood, Brownlee and Joald (1940) (*cf* Osgood, 1942) using the marrow culture method, have indicated that the effects of the sulfonamides and arsenicals are dependent to some extent on the strain of the organism, and that in some types neoarsphenamine and mapharsen are markedly more effective than the sulfonamides, especially against *Strep. viridans* A blood concentration of six parts per million of the drug must, however be maintained constantly over period of twenty-four to seventy-two hours or longer This requires at body weight of 60 kg total of 0 4 Gm. in divided doses of 0 1 Gm. each at 8 a.m., 11 a.m 2 p m. and 6 p.m. Every subsequent day 1.0 Gm. is given at 8 a.m 3 p m., and 10 p.m., and on the third day and subsequently the blood arsenic levels will indicate the necessary continued dosage. The blood arsenic determinations followed the Rankston, Magnuson and Chaney technic (1940) Mapharsen is less uniformly effective than neoarsphenamine. Regard must be had for the higher mortality of this intensive type of arsenical administration but the risks are regarded as justified.

Nongummatous septic foci should be treated surgically though if the condition of the patient is good, one or two preliminary doses of neoarsphenamine may facilitate the surgical management of the case and protect the staff in the case of an active recent syphilitic infection. In symptoms associated with gummata and with gummatous visceral processes simulating septic infection, especially in the liver treatment for syphilis produces prompt relief of symptoms while surgery may cause exacerbation (see Fig 665) Neoarsphenamine, recommended by Casuto Reucker and Chetwood in pyelitis was found by Buchtel and Cook from the Mayo Clinic, to be particularly helpful in infections of the urinary tract of coccal origin but not in bacillary pyelonephritis.

This should be of some importance in the treatment of tabetics who have complicating pyelonephritis, but for number of undetermined reasons, actual experience with the pyelonephritic tabetic is less encouraging than with other types. The drug fails in the presence of stones, marked obstruction, severe focal infection infection referable t Strep. fecalis, nonspecific prostatitis and chronic cicatricial pyelonephritis. Acidification of the urine improves the result. Small doses, interestingly enough, are as efficacious as the larger ones, and improvement will occur after the first or second injection if it occurs t all.

Syphilis and Other Spirochetoses.—Syphilis complicated by other spirochetoses, including Vincent spirillosis and pulmonary spirochetosis and pulmonary gangrene, may yield confusing therapeutic results. In Vincent infections in the mouth and throat with fever and destructive lesions suggesting rapidly progressive late syphilid, mapharsen and neoarsphenamine must be locally applied for best results. Ducbz, Weismuller, MacIntosh, Cooper and Tatum (1936) rate mapharsen as at least as effective as neoarsphenamine when used locally employing swab of 1 per cent solution of the drug with gargle of 0.4 per cent of the drug an intravenous injection of 30 mg. of mapharsen for the initial dose, and three successive intravenous injections of 60 mg. each at four-day intervals. An alkaline gargle is recommended to clear the mucosa of secretions before the mapharsen mouth-wash is employed. Rosebury Foley and Rights (1939) had discouraging results with neoarsphenamine in experimental pulmonary infections of guinea pigs, but

in man we have observed occasional clinical responses so striking as to suggest diagnosis of pulmonary syphilis. Landau, Pego and others found that clinical nonspecific improvement would take place even though the flora of the sputum presented no organisms of the fusospirillary type. The recognition of the virus pneumonias is too recent for the evaluation of the effect of antisyphilitic treatment upon them, but the unfavorable effect particularly of 606 on nasorespiratory infections with pulmonary complications (precipitation of pneumonia) should be kept in mind.

Syphilis and Arthritis.—Patients who have syphilis complicated by arthritis usually tolerate the arsphenamines well and, in fact, may derive both nonspecific and specific improvement from them. In the nonsyphilitic arthritides, however, the improvement is limited and seldom lasting, so that we have given up the effort to treat these patients nonspecifically by arsenicals in the absence of syphilis. Several reports such as that of New and Brittingham (1938) emphasize the frequency of syphilis as factor in polyarthritis, especially among Negroes in the South, in opposition to Turner's estimate of its relative infrequency in this race. Patients with arthritis tolerat mercury poorly and particularly mercury by inunction. The effect of bismuth in arthritic conditions is not yet evaluated.

Syphilis and Hypertension.—The patient with essential hypertension, in our experience, tolerates moderate treatment for syphilis well, especially if he can be kept at rest in bed which, of course, temporarily reduces his tension. Permanent ffect in the form of reduction of blood pressure sometimes results. Iodide intravenously does not seem to accomplish anything unusual for these patients. Mercury especially in the form of the insoluble salts, seems less well borne than normally It is very important that patients with rising (especially diastolic) blood pressure and coincident syphilis should be early advised and treated in preventive way for the vascular condition, fact which is apt to be overlooked by enthusiastic syphilotherapists. Reductions in weight, lowered protein and salt intake, calcium, and suitable rest and exercise should be prescribed in detail.

Syphilis, Nephrosis, and Nephritis.—The arsenicals are so well tolerated by the kidney that there need be no reasonable hesitation in using them for therapeutic tests to determine the syphilitic character of nephritis, or in the tonic treatment of concomitant syphilis. Mercury if carefully used by inunction, will not induce more than transient irritation. Under no circumstances should it be given in the form of an insoluble salt intramuscularly Bismuth, because of its much less irritative effect on the kidney is now accepted as preferable to mercury in practically all cases, except possibly those complicated by syphilitic heart lesion (see p. 209). In early syphilis complicating severe nephritis the low nephrotoxicity of the arsenicals dictates their choice. Neoarsphenamine is more nephrotoxic than 606 and there have been two reports of death from nephritis complicating mapharsen therapy rated, however, by Levin and Keddie (1944) as of small significance. A close watch must be kept of the spinal fluid for signs of neurorecurrence. Patients with a late syphilis and chronic nephritis should be treated or not in accordance with the individual indications, and with regard for life expectancy and infectiousness rather than the abstract desire to treat syphilis.

Syphilis and Pernicious Anemia.—This is dealt with in the suggestions and recommendations made on page 415.

Syphilis and Goiter.—Goiter patients with syphilis sometimes constitute serious problem. Where the basal metabolic rate is found to be definitely above normal (plus 20 or over) and the syphilis is not acute or infectious, operation is advised before treatment for syphilis is begun. The hyperthyroid patient is, in our experience, definitely and often explosively reactive to the arsphenamines, and it is much better to get him int condition to receive adequate treatment for his syphilis than to treat him without attention to the complications. On the other hand, it is worth remembering that the nervous and mental symptoms of the hyperthyroid patient may be closely simulated by those of patient with neurosyphilis and coincident goiter with slightly elevated basal metabolic rate. In such patients, in whom the full appraisal of their syphilis was not made before operation, the most violent reactions may occur pseudohyperthyroid delirium with delusions and mania, often bearing the distinctive paretic stamp. When the basal metabolic rate was not high, treatment for syphilis in such patients before operation has produced marked improvement in mental symptoms. It has, in fact, sometimes entirely dispelled the mental picture of hyperthyroidism. In all goiter patients with coincident syphilis as detected by the blood Wassermann test, and slight or moderate increase in basal metabolism, spinal fluid examination is desirable before operation. This does not, of course, apply to cases of obvious and marked hyperthyroidism as indicated by their basal metabolism, for whom operation as soon as possible is clearly essential. Netherton (1934) from the experience of the Cleveland Clinic, believes that syphilis alone can produce symptomatic pictures simulating hyperthyroidism. His review of the literature is the most complete to date. He concludes that antisyphilitic treatment should not replace surgical intervention in cases of active hyperthyroidism in syphilitic individuals, as opera-

tion followed by antisyphilitic therapy will prevent the cardiac damage which may result from unnecessary delay. Syphilis does not interfere with convalescence in these cases. Where preoperative treatment is advisable, as it often is, it should not be too intensive. Patients having neurosyphilis associated with hyperthyroidism are poor surgical risks, especially if there is mental deterioration. Preoperative antisyphilitic treatment in these cases is indicated, and is of default value especially in cases of tabes dorsalis. Gummatous thyroiditis, which we have seen operated upon before the Wassermann test was taken, must, of course, not be overlooked, although it is comparatively rare. It responds well to treatment and operation is thereby rendered unnecessary. The caution against iodide in patients with adenomas of the thyroid should be repeated. We have seen several patients with syphilis develop hyperthyroidism under treatment for syphilis, though the responsibility of the treatment was not apparent.

Syphilis and Hypothyroidism.—J. H. S. has seen one example in which the raising of the basal metabolic rate to normal in a hypothyroid patient resulted in a temporary but remarkable gain in mental acuity without treatment for syphilis. The mental picture was that of the depressed, degenerative phase of general paresis, and the spinal fluid was typically paretic. It is fair to infer that a low basal metabolic rate in syphilitic patients requires the same attention as in others. We have no records of patients with syphilis who have had low basal metabolic rates, to show the effect on hypothyroidism of treatment for syphilis.

Syphilis and Nonspecific Mental Disease.—Wezberg (1940) review of the problem of syphilitic psychoses, by demonstrating the complexity of the problem and especially of the diagnosis of general paresis on clinical grounds emphasizes by implication the unreliability of symptomatic therapeutic test results in the treatment of syphilitics with psychoses which may or may not be syphilitic. (See Chapter XX.) The treating of syphilitic patients with nonsyphilitic mental disease depends upon the general outlook of the case from the standpoint of life expectancy, infectious contacts, and the assumption of family or sexual responsibility. We have seen no evidence of any distinctive contraindications in limited experience. If the patient is likely to be returned to society, neglect of his syphilis while in the psychopathic hospital may make him a later source of danger to the public or to his immediate contacts.

The Value of Routine Serological Tests and Preoperative Arsphenamine.—It is impossible to overemphasize the worth of routine serological tests in placing the physician and surgeon on guard against risks which they may be obliged to assume but which they need not assume unawares. If it were more generally realized that operative procedures of other than an emergency character can be fully protected even in syphilitic patients by the preliminary administration to the patient of 1 or 2 small doses of an arsphenamine within forty-eight to seventy-two hours, the very serious existing risks for certain types of surgical work might be materially reduced. While certain clinics, such as that of Rochester, Minnesota, have only a relatively small amount of syphilis in their clientele and an exceedingly small proportion of it in the infectious stage of the disease, other operative clinics, especially in the field of gynecology and otolaryngology and obstetrics present a varying proportion of extremely serious risks. Student services in large cities in which women are delivered with relatively little warning and under unfavorable conditions should especially be controlled by the routine predelivery blood test for syphilis. Needle-prick infections have the reputation, largely due to Almkvist's study of "syphilis d'emblée" of being direct blood-stream infections without the warning of a chancre.

Postoperative Antisyphilitic Treatment.—While recommending the protection of the surgical staff by the preliminary administration to the patient with syphilis of two or three arsphenamine injections, it is essential to point out that as soon as convalescence is established, treatment should be pressed with the skill and determination that will bring about an ultimate cure or arrest, if possible. Too often the recognition of an intercurrent syphilis leads to the mere perfunctory giving of two or three "shots" after operation by a surgeon to satisfy a vague sense that a little something ought to be done

Fig. 213.

TO AVOID PROFESSIONAL INFECTION WITH SYPHILIS

Suggestions for the Physician

1. Demand routine preoperative and predelivery serological tests. An emergency Kline (elimination test) can be done in thirty minutes.
2. No barehand work about mouth, throat, or genitalia.
3. Nursing personnel trained to responsibility about pricked gloves.
4. Wear glasses.
5. Break finger-to-face or -nose habits.
6. Keep the mouth shut.
7. Look before entering.
8. Suspect *on your own person, the "won't-heal" lesion, the solitary lymph node* (*satellite* bubo), the indolent "infection"—especially fingers.
9. Do your thinking before, not after, a needle prick (see Fig. 214)

ABOUT NO ASPECT OF SYPHILIS IS THE PHYSICIAN OR SURGEON AS CRASSLY IGNORANT AND NEGLIGENT AS ABOUT HIS OWN INFECTION

Fig. 214.

IN CASE OF SUSPECTED ACCIDENTAL INFECTION WITH SYPHILIS IN MEDICAL PRACTICE

1. **You should know beforehand, not after,** if possible, the risks you are assuming. Routine serological tests in medical preoperative and obstetrical examinations, thorough inspection of mucosae, anus and genitalia, palms and soles, and a carefully taken history will largely protect you from unforeseen risks.
2. **Interpret the risk assumed,** before or after the accident, as follows:
   (*a*) The older the infection in the patient, the less the risk to you—after five years it is practically nil, even though his serological tests be positive. Old latent, gummatous, cardiovascular and neurosyphilis is harmless.
   (*b*) Nose, throat, and genital work is the most dangerous. Direct inoculation of blood is very dangerous only in the patient with early syphilis (first two years)
   (*c*) Recent arsphenamine treatment (up to within one to three months) usually renders the patient harmless. The earlier the case the more treatment is desirable.
   (*d*) Within forty-eight hours after an adult dose of an effective arsphenamine, a patient is temporarily harmless ("preoperative sterilization")
   (*e*) A lapse of hours greatly reduces the worth of any prophylaxis after injury; a lapse of more than a day or two renders it worthless and even dangerous ("asymptomatic carrier").
3. **If in the light of these considerations,** quickly reviewed, you believe yourself to have run significant risk of infection, proceed as follows:
   (*a*) Lay the site of the injury wide open immediately and rub in calomel ointment, 33 per cent in equal parts of lanolin and lard, for five minutes by the clock.
   (*b*) Take a "base line" *serological test on your* blood.
   (*c*) Repeat the serological test weekly for one month, biweekly for two months and then monthly for six months.
   (*d*) Some experts advise a spinal fluid examination at the end of the year, even if seronegative.
   (*e*) If the delay was too great or the risk so great as to amount almost to certainty of infection, consider outright treatment for syphilis, *versus* observation as in serological follow-up.
   (*f*) Remember that needle pricks may give rise to direct blood stream infections, and do not depend merely on watching for a local lesion.

about the syphilis. Such a course is too obviously criticizable to require comment. It frequently leaves the patient in a worse state than he was at the

outset with respect to the disease The following case is an example of this situation

Mr F H aged thirty-four years, complained chiefly of vomiting spells. He gave a history of early syphilis. Physical examination was negative. A test meal showed hyperacidity: roentgenograms of the stomach were negative. Pupils were sluggish to light, but not fixed. Serum Wassermann reaction was negative A preoperative diagnosis of chronic cholecystitis and chronic appendicitis was made and verified at operation. Relief of symptoms did not follow the operation, however and the patient was then given 2 injections of arsphenamine on suspicion, but without appreciable result. Seven years after operation he returned, stating that he had had no relief from his symptoms. The blood Wassermann reaction at this time was again negative, but spinal fluid examination showed positive evidence of syphilis of the nervous system. A diagnosis of tabetic neurosyphilis with gastric crises was made and systematic intensive treatment with arsphenamine and mercury resulted in striking improvement.

If, in view of the history of infection and sluggish pupils, a spinal fluid examination had been resorted to in the face of a negative Wassermann reaction at the time of operation, this patient's tabes could probably have been completely arrested. The two arsphenamine injections given to satisfy a feeling that something ought to be done for the suspected syphilis accomplished nothing for the patient, although the fact that his crises were amenable to treatment was subsequently demonstrated.

SYPHILIS AND TRANSFUSION

The enormous increase in the use of blood transfusion as a method of medical and surgical treatment increases while the use of stored blood (blood banks) plasma, and frozen and desiccated serum tends to diminish the risk of the transmission of syphilis The reported incidence of transfusion syphilis is in ludicrous contrast to a reasonable estimate of its frequency Rein, Wise and Cukerbaum (1938) estimated sixty-eight cases in the literature, while a fair syphilologic estimate of at least four cases known to each of 550 syphilologists in the United States would make the frequency pyramid upwards from a minimum of 2000 cases *The reluctance to report an ignominious flop* which is having increasingly serious medicolegal consequences, will probably obscure indefinitely the actual incidence of this type of medical catastrophe

The fundamental principles involved are relatively simple, and have applicability in simple clinical rules. The biologic aspects of the syphilitic spirochetemia have been considered in Chapter I. The organisms may be present in the blood within a few hours after inoculation throughout the period of active early manifestations, including chancre and secondaries and on into the period of latency Serologic tests for syphilis are known to be negative during at least the earliest part of this spirochetemic phase and this fact alone limits their value as protection against the transmission of the disease by transfusion. Physical examination of the seronegative subject may disclose the presence of a primary lesion in the seronegative phase, but on the other hand, such a lesion may be inconspicuous or even nonexistent. Since syphilis may be acquired at any time during the life of a professional donor periodic serologic testing as well as periodic physical examination is useless as a preventive The only resort is blood test and examination immediately before the drawing of blood. Rein Wise and Cukerbaum (1938) have shown both the necessity for and the simplicity of a unit procedure covering simultaneously blood typing and the detection of syphilis, utilizing the ultrasensitive Kline exclusion technic whose simplicity and rapidity is such that the entire work-up of the transfusion donor including his immediate physical examination need not occupy more than thirty minutes No laboratory which examines the blood of donors can be considered completely equipped which

cannot carry out this procedure on every single donor and which does not provide a twenty four hour service for the purpose. The Kline finger puncture blood test procedure avoids the objection of donors to a double venipuncture

The advent of the blood bank and refrigeration and desiccation methods of handling pooled transfusion material tends toward relaxation of ideal precaution for the prevention of transfusion syphilis. Such relaxation is justifiably and vigorously opposed—first, because citrated blood when fresh is as effective in transmitting syphilis as whole blood. A storage of not less than forty eight hours (Turner and Diseker 1941) is necessary for the disintegration of the organism, and storage of four days or longer is the more desirable. It is apparent therefore that transfusion from blood bank unit, made up within the four-day period, which contains an increment of blood from syphilitic donor may transmit the disease. Refrigeration is a much less efficient protection than is generally supposed (Bloch, 1941) but survival of the organism after ninety-six hours at 4 Centigrade has been demonstrated. Even after ninety-six hours heavily infected blood like that of early syphilis may still be dangerous. Turner Bauer and Kluth (1941) found that *Treponema pallidum* and probably *Treponema pertenuis* are probably killed by the process of freezing and desiccation, even though by this method the viability of many bacteria and viruses is retained. Transfusions prepared from desiccated blood serum or plasma are probably without risk with regard to transmission of syphilis or yaws, even though the material is obtained from an infected donor

It must be clear therefore that the safe period for an infected blood or blood plasma cannot be less than four days after storage begins, and may well under some circumstances, especially refrigeration be longer

Emphasis on the occasional emergency situation in blood transfusion, less important since the use of banks, has led to number of suggestions for the destruction of *Spirochaeta pallida* possibly present, through chemical means. Kast, Peterson and Kolmer (1939) working with neoarsphenamine, demonstrated the safety of blood to which 10 mg of the drug per 100 cc. of citrated blood had been added. *Eichenlaub, Stolar and Wode (1941) suggested 10 mg.* mapharsen for each 500 cc. of sodium citrate, used in preparing transfusion blood. Quinine di-hydrochloride (Salkine, 1931) in 1 1000 concentration, has been suggested, but the storage time after the quinine was three days which may have resulted in self-sterilization of the blood

The use of cadaver blood has been advocated by Yudin (1936) where it can be available, t large centers, where the bodies of persons killed in traffic accidents and dying of thrombosis and angina pectoris especially can be available. Such blood can be stored for three weeks, but it would seem that the principles and objections pplicable to blood of living subjects are applicable to individuals recently dead.

As a statement of general principle, then, blood banks should contain only the blood of normal persons regardless of experimental work and protective bacteriostatic and spirocheticidal agents, the primary responsibility of those in charge of a blood bank is to see that the blood of syphilitic persons is excluded by every known test-precaution. The qualifying considerations above described, relative to period of storage and addition of spirocheticidal substances can have application only to emergency situations. There are unquestionably risks involved in attempting to protect any form of blood bank against contamination by *Spirochaeta pallida* by the addition of arsenoxide or an arsphenamine. There is therefore, no substitute to offer for the requirement of adequate blood serologic tests for syphilis for all donors on each and every donation of blood. Periodic taking of blood tests at *stated intervals* is not sufficient because it is clearly recognized that serologic tests may be negative even in the presence of spirochetemia in the incubation stage and early course of syphilis Every donor of blood for transfusion whether by bank or otherwise should, furthermore, be subjected to close physical inspection of the oral mucosa, trunk, anus and genitalia for the presence of suspicious lesions The only type of accumulation procedure for storage of

blood which can be regarded as literally free of risk of transmitting syphilis regardless of time factors is that of complete desiccation. Refrigeration alone cannot protect against every contamination possibility

It will be clear therefore that the gain in diminished risks of syphilis transmission by the newer developments in blood storage is relative and not absolute and that the precautions appropriate to direct transfusion and citrated whole blood are still in order

Medicolegally according t an opinion of the Burea of Legal Medicine and Legislation of the American Medical Association (1945), the liability of a physician who gives a transfusion with blood of a syphilitic donor the patient contracting syphilis, has not been fully explored by any court of ppellat jurisdiction. In the bsence of acut emergency the physician who uses untested blood of donor for a transfusion and thereby transmits syphilis t the recipient should be prepared in case of suit, t justify his actions by convincing evidence that in pursuing the course he did be xercised that reasonable degree of skill, knowledge and diligence ordinarily pos-

Fig. 215

DON'TS FOR BLOOD TRANSFUSION

1 Don't be panicked int calling a transfusion an emergency justifying slipshod consideration of syphilis, if thirty minutes for typing, physically examining, Kline finger-blood exclusion testing of donor is available.
2. Don't rely on a blood test alone t clude syphilis.
3 Don't cept member of th family as *pro facto* free of syphilis—even t mother and child. Check everyone even yourself The family member delusion is the worst pitfall of ll.
4 Don't trust any form of periodic test or examination of donors. Examination must be immediate, complete, before each donation.
5. Don't use banked blood stored less than four days.
6 Don t even in extreme emergency give an unchecked donor blood or seropositive latent blood (M Namara) without adding neoarsphenamine 10 mg. per 100 cc or mapharsen 0 01 mg. per 500 cc. Have it in your field kit.
7 Don t use kno n or suspected syphilitic or syphili seropositive blood for banks or plasma (unless desiccated)
8. Don't use th blood or body fluids of syphilitics, known or suspected, for any biologic treatment purpose (convalescent serum, et) unless effectively sterilized, or over five day old.
9 Don t fail t carry insistence on vigilance and detail in this matter out t the extreme periphery of our personnel, round the lock. Syphilis rides in on Default in the small hours.

sessed and exercised l *physicians under the same circumst nces, that is burden of proof* that physicians had better void rather than ttempt t meet. In the case of an acut emergency physician may be faced with the choice of using the blood of an untested donor thereby running the risk of transmitting syphilis t the recipient, or refusing t use the untested blood and thereby assuming the risk that his patient ill die because of that refusal When faced with such choice the alternative should be fully explained t the patient or t someone authorized t ct for him, leaving the decision t the patient or other responsible person to exercise his or her ow judgment n accepting or rejecting the blood of the untested donor The consent or rejection should if t all possible be reduced to writing. Where the patient cannot make a rational decision and where no other uthorized person is vailable to act in his stead the emergency being acut it is difficult t conceive of a court condemning physician for adopting necessary procedures t save a patient lif After all, syphilis curable lif extinct, is extinct. A California court has held that the paramount duty of physician is t save his patient lif even if some injury may result to the patient in the process.

As knowledge and facilities for the pplication of reasonable precaution to the protection of the patient receiving blood transfusion become more idely disseminated, standards more familiar nd the blunderingly inexcusable character of most of the mistakes made more apparent

the position of the physician who is responsible for the transmission of syphilis by transfusion will become increasingly and justifiably more precarious.

SYPHILIS AS A COMPLICATION OF SURGERY

This topic is of course repeatedly discussed from the diagnostic standpoint in subsequent chapters and is illustrated by numerous case examples. Patients with syphilis who have been effectively treated can be operated on with impunity. Untreated patients develop postoperative difficulties apparently attributable to their syphilis in from 7 to 10 per cent of cases exclusive of those in which the surgeon incised a gumma. Following operative trauma to an active gummatous lesion, which is tantamount to a diagnostic error on the part of the physician or surgeon, unfavorable results and an extension of the process may be expected.

Philip (1940) found that syphilitic patients, even though they had been treated with six arsphenamine injections, still showed nearly 10 per cent more wound infection than a control group of nonsyphilitics. Falk and Kempner (1941) confirmed this in a large series of laparotomies among Negroes, but believed the differences to be of small significance. Eviscerations and fecal fistulas in their experience had no apparent relation to the presence of syphilis, but they conceded that the latent form of the disease provides a slight additional risk as far as both wound healing and morbidity are concerned.

On the other hand, the behavior of the operative wound made in healthy skin even of undoubtedly syphilitic patients has been investigated by Goeckermann from Mayo Clinic experience and more recently by Scheffey. Both observers agreed that in the overwhelming majority of cases the surgical wound heals kindly and without complication attributable to the syphilitic infection.

Longstanding syphilis makes the patient a poor surgical risk in proportion as it affects his tissues and structures in general. He is no worse risk on this score than another patient with an equal amount of damage from some other cause. From the standpoint of the patient, an injection or two of arsphenamine before operation may or may not have an unfavorable effect upon his postoperative course. The case must be considered individually and the danger of setting up a therapeutic shock (Herxheimer) reaction, or doing damage to the cardiovascular or nervous system which will compromise the postoperative course must be considered. This, however, is not to be taken as minimizing the value of carefully considered adequate treatment for syphilis before operation in patients who do not present a surgical emergency. There can be no doubt that the large majority of patients with late syphilis can sustain operation for nonsyphilitic conditions without complications attributable to any effect of their syphilis. Goeckermann found that the chief difficulty in the relation of surgery to the untreated syphilitic patient was one of overlooking or not considering the syphilis in connection with the case as a whole and particularly with reference to diagnosis as illustrated by exploratory procedures. In 5000 surgical cases even a blood Wassermann test was taken in only 1600. The incidence of syphilis thus discovered was 0.46 per cent of the 5000 cases as against an expectancy for all the patients of the Mayo Clinic of more than 3 per cent. On the presentation of these facts to the Clinic it was made a rule that blood Wassermann tests were to be taken routinely on all patients before operation to assist in the recognition of gummatous

lesions and to make it possible to consider their syphilitic infection as part of their medical and surgical problem.

Wile (1938) has emphasized the importance of simultaneous antisyphilitic treatment in the surgical management of syphilitic osteomyelitis. He points out that gumma of the testis and gumma of the spinal cord are two notable exceptions to the rule that it is unwise to operate on purely syphilitic conditions. Both processes develop so rapidly that to anticipate their worst effects, operation should proceed, but be immediately followed by adequate treatment for syphilis. This is also true of gumma of the eyeball and osteomyelitis of the small bones of the head. Wile emphasizes cicatricial contraction as legitimate field for surgery in the presence of syphilis, and points out little recognized occurrence of plastic peritonitis, when abdominal operations are performed on latent syphilitics who have not been previously treated. Wiltrakis, Partipilo and Olsman (1941) found that surgical results in patients preponderantly with neurosyphilis presented somewhat higher mortality rate which on analysis, however did not seem to indicate that the risk in the neurosyphilitic is notably greater than in nonsyphilitics. Local surgical complications of the nature of wound infection, were more common in neurosyphilitics, but sloughing, evisceration and gumma formation did not occur If syphilitic patients had had adequate antisyphilitic treatment in the past, it provided the necessary insurance against bad effects without the necessity for further immediate treatment.

LOCAL TREATMENT OF SYPHILITIC LESIONS

The Chancre—The first principle of all local treatment of the chancre is a negative one. Do not make any applications other than physiologic salt solution or institute any systemic treatment for a suspected genital lesion, or in fact any genital lesion until a systematic and repeated search for *Spirochaeta pallida* has been made preferably by darkfield Excision of the chancre is neither necessary nor advisable, inasmuch as the removal of a merely incidental focus among the thousands of others already existent seems useless It is pointed out that the chancre is a site of recurrence at times, but we have not been able to convince ourselves that its recurrence is a solitary affair It is usually simply a part of a general recrudescence of the disease (For local treatment of other or complicating genital lesions see p 508 *et seq*)

Mouth and Throat Lesions.—Local treatment of mouth and throat lesions and the silver nitrate stick, against which Fournier spoke so frequently as a source of mediate transmission, have become unnecessary with the advent of the arsphenamines Ordinary cleansing measures are all that is called for between the time arsphenamine treatment is begun and the time the lesion heals. The disappearance of pain and secondary infection from a crateriform pharyngeal ulcer following arsphenamine treatment in a patient made cachectic by inability to swallow ranks with the astonishing transformations seen in the treatment of gastric syphilis.

Cutaneous Lesions.—Cutaneous syphilids rarely require more than a few days of wet dressings with potassium permanganate solution (1 4000) or boric acid solution, before healing takes place under arsphenamine In occasional extensive cases small clipped grafts may hasten the covering of denuded surfaces after the granulations have become clean. The noncontractile character of the syphilitic scar makes the deformity usually less than is expected. Thiocresol (Sulphen) may conceivably be employed to hasten granulation in large destructive or excavating syphilitic lesions but such steps are rarely necessary In fact, failure of a syphilitic lesion of the skin or subcutaneous tissue to heal with rapidity at once raises the question of malignancy rather than syphilis

Gummatous Lesions.—Osseous syphilids occasionally require the removal of sequestra for complete healing and special operative measures may be

needed in gummatous osteitis of the skull This should not be done until after treatment control is fully established, but, on the other hand should not be too long delayed The incision of gummas and their surgical removal is usually undertaken either on an error of diagnosis or under the mistaken conception that such lesions are the better for removal. Fibrous gummas of the meninges or brain may require removal as tumors With modern methods of treatment, operation on gummas in soft tissue except possibly the broken-down and septic gumma of the liver is usually needless and in fact, sometimes inexcusable

CHAPTER XI

THE DIAGNOSIS OF EARLY SYPHILIS—THE CHANCRE

The Diagnosis of the Chancre No Longer a Clinical but a Laboratory Problem.—The progress of venereology since 1904 has relegated farther and farther to the background the distinguished but one-sided French tradition of the morphologic diagnosis of the chancre. The clinical appearance of the primary lesion to which Fournier devoted so much descriptive eloquence remains a useful drill and a critical or collaborative instrument in what is no longer a clinical but a laboratory problem. Over-emphasis on the physical characteristics of the chancre has led in the past to innumerable errors of diagnosis. Leading all other determinants in the diagnosis of primary syphilis is the darkfield identification of *Spirochaeta pallida*. As an adjunct subject to critical interpretation, the positive blood serologic test for syphilis stands next. Bringing up the rear is the ancient fellowship of half-truths about induration, erosion, multiplicity, painlessness and so forth, which constitutes a clinical dialectic and occasionally assumes importance where no other help can be had but as a basis for diagnosis clinical criteria as such have gone to pot.

Today modern intensive therapy and the outlook for radical cure condemns unhesitatingly a system of diagnosis which, by increasing the value of the later instead of the earlier lesion, "loses the patient any part of his chance.

The art of morphological diagnosis in primary syphilis survives in those cases in which a concomitant syphilis is accompanied by nonsyphilitic lesions suggesting chancres. The diagnosis of chancroid, let it be emphasized, is no longer positive but negative despite the newer methods of diagnosis. It consists in eliminating syphilis.

Is the Chancre Becoming Rarer?—This question, inseparably linked with the epidemiology of syphilis, cannot be categorically answered. That there has been a decline of infectious syphilis of the primary and secondary types has been attested by the experience of the University of Pennsylvania Clinic, the Cleveland City Hospital Clinic and numerous observers speaking informally. Reiter (1934) found that in the German Navy there had been a 45 per cent decrease in primary and secondary syphilis since 1927. Lomholt records that in Denmark fresh infections fell from 4500 in 1919 to 700 in 1933 (1935). Blakley and Levin (Cleveland 1938) found that from a peak of 419 new infectious cases in 1926, there was a steady drop to a low of 92 in 1937. Chancroid on the other hand, wavered up and down between limits of 190 and 11 over the same period. Lymphogranuloma venereum, coming to recognition as a disease in 1931 by Frei test, ran a steady 80 to 90 cases per year to 1937. The experience of the University of Pennsylvania clinic shows a drop in the percentage of infections to all other types of syphilis seen between 1931 and 1941 inclusive from 24.4 to 8.9 per cent. In 1942 an unexplained 4 per cent rise occurred. The experience of individual clinics is so obviously conditioned by special circumstances affecting their clientele that almost any figures can be matched against their opposites in various parts of the country and various countries of the world.

The question of what has become of early infectious syphilis is too complex to be answered by any one set of figures. The partition of the case material between private practice and clinics varies with economic conditions and with the interest in and ability of the private practitioner to hold and treat, if only for a short period, the primary syphilis brought to his attention. There is some reason to suspect that primary syphilis is at intervals replaced by infectious relapse in the infectious syphilis category as the result of the inadequate treatment of early syphilis which presents itself to the practitioner and which he cannot hold to adequate treatment. The incidence of symptomless infection is a riddle as yet answered only by individual speculation. The question

is being raised as to whether the initial lesion of syphilis and the secondary eruption are really disappearing from the field of medical practice or whether some change is taking place in the disease itself, or some result being secured by dissemination of knowledge regarding treatment, which is gradually causing these outspoken manifestations to become increasingly rare. In comparing notes with other clinicians there is a general agreement, which our own experience confirms, that the early manifestations are being seen in clinics less frequently than they were ten years ago. Part of this may be attributed to the actual decline in the incidence of syphilis as a disease which is indicated by such statistical estimates as are appearing in the English and German literature. Part of it, no doubt, comes from the readier use of the arsphenamines by the practitioner whose patient no longer reaches the clinic until he has had at least 1 or 2 injections. Part of it may conceivably be due to a change in the disease itself, which may be productive, on the one hand, of less conspicuous early manifestations, and, on the other of more frequent involvement of the nervous system. The recognition of extragenital lesions, so far as we have observed, seems not to have kept pace with the identification and consequent disappearance of the genital chancre, a point also noted by Morton Smith. The inconspicuous genital chancre, the syphilis without chancre, the "bubon d'emblée," and the extragenital undiagnosed chancre seem distinctly more numerous than in the past by contrast with the apparent decline of the genital lesion.

Fig. 210.

THE PHYSICAL CHARACTERISTICS OF THE PRIMARY LESION OF SYPHILIS

1. The chancre tends to be single rather than multiple
2. It has a relatively long incubation period (twelve to forty days)
3. The lesion if uncomplicated tends to be relatively painless (chancre of the finger may be an important exception)
4. There is induration of the base of the lesion.
5. Erosion of the surface is the rule rather than ulceration.
6. The border tends to be sharply defined, shows a fine hemorrhagic line at the periphery and is not undermined, ragged, or necrotic in uncomplicated cases.
7. The base tends to be clean, with a faint grayish pellicle, or a raw muscle color
8. The exudate is serous rather than purulent.
9. The chancre tends to be indolent and to run a slow course—three to eight weeks.
10. A painless, non-inflammatory discrete enlargement of the adjacent lymph-nodes, usually bilateral, develops after the first appearance of the lesion, and in about 70 per cent of the cases.
11. A notable exception to the bilateral character of the satellite adenopathy is the extragenital primary lesion, in which the adenopathy is usually unilateral.
12. On healing, a thin atrophic, often practically invisible, scar remains.

Long Incubation, Indolence, Slow Course and Satellite Adenopathy are the Outstanding Features of the Chancre in Diagnosis.

The Diagnosis of the Primary Lesion of Syphilis is a Laboratory Not a Physical or Morphologic, Problem.

The Evolution of the Chancre.—Formally speaking, the chancre is the first recognizable syphilitic lesion. It begins invariably at the point of inoculation. Morgan has shown that less than 50 000 organisms will not produce lesions in rabbits. Less than 1/150 cubic millimeter of chancre fluid will probably infect some persons. Shaw (1041) failed of infection after prophylaxis following a needle prick with chancre fluid (rabbit) containing 8 *Sp pallida* per oil immersion field. In theory the local reaction after a rather prolonged but somewhat indefinite period of incubation begins as a macule which develops into a papule. The accepted physical characteristics of the primary lesion are summarized in Fig. 210.

No one of these characteristics has independent weight, but derives all its significance from combinations with the others. For example while the single chancre is typical exceptions to the rule are now so commonly recognized that they have ceased to excite comment. As high as 20 chancres have

been reported in a single case (Almkvist) and 2 3 or 4 are common, especially where the infection begins in previously existent multiple lesions such as herpetic vesicles, scabetic burrows etc.

The chancre grows to size and conspicuousness dependent upon the virulence of the organism, the resistance of the tissues, the site and mode of inoculation, the degree of secondary infection, and the intensity of the local reaction. In size alone the chancre may vary from that of millet seed to an ulcerating tumor mass of 10 cm. in diameter or giant plaque involving the entire anterior aspect of the scrotum. The typical chancrous papule passes through series of clinical evolutionary stages corresponding to the tissue and general immunological reactions

Fig. 217 —A morphologically typical Hunterian chancre of the prepuce. The lesion is not chancre. The induration, base border and discharge were in every way characteristic. The lesion developed two weeks post coitus. It developed in tabetic with positive spinal fluid, though negative blood Wassermann reaction. (He thought himself immune.) Repeated darkfield examination was negative. The inguinal glands did not enlarge. The lesion was excised and the tissue examined by Dr A. S. Warthin for *Spirochaeta pallida*, with negative results. The histology of the lesion was that of simple inflammatory process This as not the sit of the original primary lesion so that it could not have been pseudochancre redux. The patient never developed further signs of re- or superinfection The case illustrates the fact that lesion may be typical chancre without being chancre.

described in Chapter I. A local edema followed by lymphocytic infiltration gives to the papule an unusual degree of shottiness and induration. Plasma cells are found in the infiltration, often in large numbers, and some fibroblastic proliferation occurs. The peripheral obliterative endarteritis results in superficial necrosis and destruction of epidermal surface which, at times, may be so marked as to give rise to definit slough. As rule, however an uncomplicated chancre is an eroded rather than an ulcerative lesion. This erosion in typical lesions yields serous exudate which on exposed surfaces forms thin, grayish-yellow slightly hemorrhagic crust (Fig. 8) The base of the erosion or ulcer is smooth. The border is usually regular and smooth, not raised, rolled, scalloped, or pearled. A distinct hemorrhagic or dark red line can sometimes be seen around the margin of the erosion. The lesion is usually relatively painless, but this most deceptive characteristic cannot be trusted at all. As the infection spreads locally from the site of reaction various

important concomitant phenomena, such as local lymphadenitis and sometimes lymphangitis, appear (Figs. 218, 219) With the progress of the local reaction, healing and fibrosis gradually set in. The epidermis rapidly regenerates over the erosion and healed plaque remains. The lymphocytic infiltration, which gives the plaque its induration, subsides much more slowly than the healing of the erosion and may remain for some time to mark the site of the active lesion. Spirochetes are present in the deeper portions of this infiltration and about the neighboring vessels, representing the remnants of the organisms largely destroyed by tissue reaction. The induration finally subsides, leaving no trace of the chancre, or there may remain at most only the most superficial and minute scar The impression that conspicuous scar means previous chancre is widespread error The uncomplicated chancre seldom leaves definitely recognizable scar in tissues which are naturally lax and flaccid. The accompaniments of the chancre in the form of satellite adenopathy and lymphangitis are important and are specially discussed below

The Hunterian or "Typical" Chancre.—While the expert, such as Fournier recognized and allowed for the tremendous variability of the primary lesion of syphilis, the verage physician has carried, from his text-book days, verbal photograph of the so-called "Hunterian chancre as his concept of the onset of syphilis. If lesion on the penis were solitary round or oval, had firm button-like cartilaginous indurated base convex eroded surface with raw-ham color

Fig. 218.—The bilateral discret inguinal adenopathy (satellite bubo) of the genital chancre The visibility of the nodes is increased by special lighting This young man was not ware that he had chancre or even genital lesion, and came for different complaint. The primary lesion is represented by thickening or sclerosis of the right margin of the prepuce, without erosion, ulceration, pain, discharge or other symptom. The lymph nodes are painless, firm, elastic, moderately enlarged and discrete. There as no secondary eruption, but the blood Wassermann reaction was positive. *Spirochaeta pallida* was present in the sclerosis.

thin serous discharge and hemorrhagic border not undermined, it passed as chancre with the verage observer (Fig. 217) If the lesion came on fourteen to twenty-one days after intercourse was painless, accompanied by discrete swelling of both chains of inguinal lymph nodes, the diagnosis was certain. But if one or two of the dozen or more variations possible were to occur, the lesion would be diagnosed chancroid, chaf hair cut, cold sore, etc. Experience with the late syphilis that follows misdiagnosed primary lesions and the masquerade under which its onset passed even critical inspection up to recent times, soon teach the comparative worthlessness of the purely clinical diagnosis of the chancre.

Syphilis without Chancre (Syphilis d emblée).—The new facts of great importance to the clinician which have come to light within recent years regarding the invariability with which a chancre will develop at the site of inoculation of *Spirochaeta pallida* (Fig 219) have been discussed from the immunological standpoint in Chapter I. So-called "syphilis d emblée" or syphilis without chancre has been a well recognized entity for a number of

years It was generally accepted however as the consequence of direct inoculation into the blood and was considered to be one of the rarest of syphilological accidents There exist quite definitely authenticated cases of puncture inoculation from needle pricks which appear to be true examples of syphilis d emblée On the other hand Almkvist in 1913 critically examined 23 reported

A

B

C

Fig 219 — An insignificant primary lesion of syphilis at the meatus. This patient was under observation following the finding of lat secondary eruption in his if (ho was infected from another source) Repeated examinations ere negative Six eeks after he was first seen the Wassermann, taken as matter of precaution, as returned positive Even with this guide his primary lesion was not discovered until the slight enlargement of the inguinal nodes, shown in A, was recognized. A the foreskin as dra n back the pipestem lymphangitis of the dorsal lymph channel was revealed (B) The slight pouting of the meatus (C) no more than ould have been produced by an irritating urine and totally thout induration, as then suspected, and on scraping the end of the intact penis the *Spirochaeta pallida* as recovered. The lesion was probably at this time about tw t three eeks old

cases of yphilis d emblée of which only 4 were accidental Needle-prick inoculations alone seemed to tand a searching analy is

The literature including articles by Lane Gottheil, Fordyce Hazen, and Feldman, consists largely of case reports in hich no particular distinction is drawn between hematogenous and local cutaneous inoculation. A critical analysis by Tièche subdivides syphilis d emblée into two types, hematogenou and lymphogenous, the former following blood transfusion (see p. 470)

The lymphogenous type may become manifest only in the form of inflammatory lymph nodes with an entire absence of visible primary lesions, though Tièche believes that minute initial sore may exist, unobserved by the patient. *A priori* there seems no intrinsic reason why the local tissue reaction to the organism need rise to the threshold of clinical recognition and experimental study has now shown that chancreless syphilis need not be even rare. Pollard reports what may well have been such case in a man who, although under close observation, apparently developed no more than *fugitive erythema at the meatus, followed at the usual interval by the appearance of secondaries.* This case is practically reduplicated by Fig. 219. Audrey and Chatelier have called attention to the complete change in the clinical onset of syphilis which may follow the engrafting of the spirochetal infection upon surface already ulcerative as result of some other type of primary infection. In cases of this type the only clinical manifestation may be the local lymphadenitis. This type of reaction is especially apt t occur in the mouth and throat, and furnishes highly perplexing clinical picture (see Fig. 248). Brown and Pearce have shown that inoculation upon the mucous membrane in the rabbit gives rise at times t practically imperceptible reactions, hich are none the less followed by general infection.

Fig. 220.—Indurated scar of chancre concealed in the pubic hair but identified after finding the satellite bubo. The lesion had developed at the lower angle of a fresh herniotomy scar and the patient was entirely unaware of its existence. He ppeared with florid secondaries.

While there can be no reasonable question of the existence of syphilis d emblée, and while it is a strong presumption that generalized syphilis may develop without a local reaction at the site of inoculation such cases should not discourage the clinician from making the most vigorous search into every out of-the-way corner of the body for the site of primary reaction to the infection in any given case. Every physician should be impressed with the fact that a chancre may assume almost any conceivable morphological form, and may occur on any accessible portion of the human body except the teeth, hair and nails.

Deceptive Incubation Periods.—The long incubation period ascribed to the chancre may be wholly deceptive in a negative way in that a short incubation may simply be that of a superposed banal infection such as a chancroid beneath which the chancre subsequently develops. Double infections with chancroid and syphilis thus appear not infrequently to have the short incubation of the chancroid but the long course of the chancre When the

base of a "chancroid" becomes clean and indurated a darkfield from serum aspirated from just beneath the lesion may show *Spirochaeta pallida*. Lesions whose incubation period is over ten days are definitely suspicious

Fig 221—Multiple chancres developing in the burrows of the itch mite (scabies). Darkfield positive

Fig 222.—A chancroid, so proved by negative spirochetal findings, positive Ducrey streptobacillus smear and negative follow-up for syphilis. There is a gangrenous type of chancre which may closely simulate this lesion.

Slow Healing and Prolonged Course.—Lesions which are the sites of syphilitic infection present, more often than any others, a combination of indolence with a prolonged course "It wouldn't heal" is the most common descriptive phrase obtained in naïve discussion from the patient. This con

trast between the mildness of the reaction and its long duration and obstinacy is, we believe one of the two characteristics of the chancre which

Fig. 223.—The pseudochancre redux, a gummatous recurrence at the site of the original chancre. No spirochetes can be found by darkfield, and there is seldom any associated enlargement of the adjacent lymph nodes. Note in this case the nodulo-ulcerative syphilid of the right wrist and the scattered nodules on the left.

Fig. 224.—A superficial ulcer of six weeks duration on the glans. The base was clean, the discharge serous or serosanguinous, the lesion only slightly tender There was bilateral inguinal adenopathy The border of the lesion was just sufficiently rolled to arouse suspicion, and a shaving removed from the edge before any attempt at darkfield examination showed the lesion to be squamous celled epithelioma. It had developed on a leukoplakial surface in a man of fifty years. Exposure other than marital was denied. The inguinal nodes were already involved.

has best withstood the revision of our clinical criteria by the more accurate and searching test of the darkfield

Induration.—Induration (Figs. 232 233) is the classical sign and makes the most impression on the beginner It involves the base of the lesion, results from edema and the packing of the tissues with lymphocytes and varies from the "visiting card" or parchment induration, barely palpable by the expert and the cartilaginous button slightly larger than the base of the ulcer to the brawny wooden induration of the giant chancre of the lip (Fig 225) or the rubber-ball induration of the phymotic chancrous infiltration of the redundant foreskin. Spurious or factitial induration not due to syphilitic infection has long been recognized and is likely to be confusing in lesions which have been subjected to irritative treatment, especially with chemicals or the actual cautery In a lesion which has been subjected to such treatment, induration is without clinical significance and must be absolutely dismissed for the time being from the list of criteria

Erosion vs Ulcer—It is more characteristic of the other infections with which the chancre may be confused, such as chancroid (Fig 222) infected herpes progenitalis, treated erosions, secondary pyogenic infections, gum

Fig. 225 —The giant chancre of the lip brawny wooden, phlegmonous induration with marginal ulceration. (Collection of F G Harris.)

matous recurrences (pseudochancre redux—Fig 223) and malignant lesions, that they produce not erosions, but ulcers (Fig 224) On the other hand, this criterion has now been shown so many times to be common to insignificant lesions, and lacking in what subsequently prove to be true chancres, that no attention can be paid to it.

The Border—In the typical chancre the border is flat not elevated or rolled and the transition from the slightly convex surface of the erosion is at times almost imperceptible A frequently observed feature is the slightly hemorrhagic line of dilated capillaries (Fig 220—new formation of capillaries) about the margin of the erosion Undermined borders suggest secondary infection of the chancre or that the lesion is a chancroid phagedena or tuberculosis. The border has relatively little weight in differential diagnosis in the light of modern knowledge

The Base—A typically indolent chancre usually has a clean base A thin grayish pellicle forms if it is moist or protected (see Figs. 232 and 237) Where the lesion occurs on the exposed skin a crust usually forms but this on removal shows a relatively smooth base (see Fig 217) Secondarily infected and

true chancroidal ulcers are much more apt to be rough dirty and necrotic, and covered with purulent exudate (Fig 222) On the other hand it is entirely possible for the chancre to have a necrotic base and clinical lesions resembling

Fig. 226.—A false induration developing in lesion about the fourth week after the frenum had been destroyed by the ulcer Not the clean base and hemorrhagic border suggesting chancre developing on the base of chancroid. The lesion was proved nonsyphilitic by repeated darkfield examination, aspiration of the base, and four months of observation and Wassermann follow-up.

Fig 227 —The remnant of the glans penis following gangrenous balanitis. The corpora cavernosa had sloughed away over the end of the penis to their ttachment at the crura. This patient, sixty-three years of ge also had syphilis, but it was probably a lat infection rather than coincidence of primary lesion and gangrenous balanitis.

chancres with necrotic bases but showing no signs of being syphilitic have been ecognized.

Phagedenic Genital Lesions.—Necrosis is the characteristic *par excellence* of the group of lesions included under the term "phagedena and gangrenous balanitis (Fig. 227). In the latter

condition especially which is an infection with Vincent symbiosis of large spirochete and fusiform bacillus, gangrene may be wholesale and take place with terrifying rapidity amputating the genitalia (Fig 227) or involving the corpora cavernosa of the penis from the glans to their insertion into the pubes. For some reason the glans and the corpus spongiosum have been relatively resistant in the cases we have seen. It is rare but not impossible for syphilitic infection to be engrafted upon lesion of this sort.

Satellite Bubo —The lymphadenitis (Figs 218, 219 228, 230) associated with the development of the chancre is one of its most constant and characteristic features With the indolence and slow course, and to a less extent the induration, it has *survived the critique of darkfield practice and stands* today as one of the most unvarying and trustworthy of the few remaining clinical guideposts in the recognition of the disease. Fournier rated it as without question the most valuable sign of the chancre, and begins an entire chapter devoted to its consideration by the vivid words of his preceptor Ricord "Il est le compagnon fidèle du chancre il l escorte invariablement, fatalment il suit le chancre comme l ombre suit le corps. Pas de chancre infectant, sans bubon, voila ce qu on peut donner hardiment comme une loi pathologique. Exceptions, however are not so rare as the purely clinical evidence would suggest Approximately 30 to 40 per cent of primary lesions in our experience at the time the chancre was identified by laboratory evidence, did not present a clinically significant associated local adenopathy Even with this qualification the "satellite bubo" remains an extremely important suspicion arouser "

The satellite bubo almost invariably involves the nearest group of lymph nodes to the lesion. One of the occasional exceptions in our experience has been the escape of the epitrochlear node in chancres below the elbow and the appearance of the bubo in the axilla, a point to be borne in mind in lesions on the fingers. The adenitis like the chancre is characteristically indolent in uncomplicated cases, though benign secondary infection and the Ducrey streptobacillus may as secondary invaders, altogether alter its course. Enlargement of the nodes seldom begins before the seventh day of the life of the primary lesion, so that it has little diagnostic value in the very period when the chancre most needs to be recognized and yet offers the least to make its clinical identification possible The recognition of chancres by darkfield examination before the fifth to the seventh day of course, anticipates the presence of an adenopathy The involvement is usually bilateral in lesions about the genitalia, and unilateral elsewhere, even in lesions near the median line The process about the genitalia involves a whole chain of nodes rather than a single node and this pleiade" or chain was rated by the French syphilographers as one of the most characteristic features of the chancrous bubo The individual nodes are usually discrete firm but not hard move freely beneath the skin, show no signs of inflammatory character in the form of matting with other nodes or erythema of the surrounding skin, and are practically painless. Secondary in vasion at once modifies the entire picture and softening or suppuration may then take place. We have been unable to confirm from our own experience Fournier s statement that the satellite bubo in lesions in the mouth and about the neck is especially apt to show periadenitis with softening and a tendency to suppuration We have never seen a suppurating cervical satellite bubo even under conditions most favorable to infection. Lymphangitis of an indolent sort is occasionally observed especially in some chancres of the penis, in which the central dorsal lymph channel exhibits a

marked degree of involvement usually spoken of as "pipestem lymphangitis (Fig 219)

Adenopathy in Malignancy—The time element in the development and course of the local adenitis is especially important in the differential diagnosis of malignancy (Figs. 237 238) The satellite bubo appears earlier in general than the adenopathy of metastatic malignancy the former developing in the first to second week, and reaching the maximum usually by the third or fourth week; the latter not being present t all at outset unless marked secondary infection occurs, and only appearing after lapse usually of several months. The dangers of attempting differential diagnosis on this basis, however become so pparent as one clinical experience grows, that it is safer to resort to darkfield and tissue study than to waste time in arguments about so uncertain distinction.

Local Adenopathy as Guide to the Location of Healed Chancre—One feature in the chronology of the bubo is of much importance, however This is its persistence beyond the time of beginning healing of the chancre It may last for eeks or months, and in the case of more than one patient with an unrecognized or healed primary lesion and evidence of fully developed recent infection, it may serve as guide to the region in which the chancre developed and lead to the identification of its scar (Fig 240)

Fig. 223.—The unilateral satellite bubo (below the left ramus) in chancre of the upper lip.

Variations in Local Adenopathy—The satellite bubo, apart from its variations under conditions of intercurrent infection and treatment of lesions, presents intrinsic variations ranging from complete absence to giant tumefaction suggesting Hodgkin s or malignant lymphoma. Fournier is authority for the statement that there are no important variations in the two sexes There seems to be no necessary relation between the size or character of the primary lesion and the size of the satellite bubo under ordinary conditions of inoculation. The group of cases reported by Audrey and Chatelier under the title "Bubon d emblée, syphilis cryptocarcinique" furnishes an important variation on this statement These authors report five cases in which, under the clinical appearance of malignancy of the tonsil and pharynx, enormous satellite adenopathies developed which from the subsequent course of the cases proved to be the satellite bubos of extragenital syphilitic infections which did not develop anything to suggest typical chancres. In this connection it is very important to recall the possible errors in pathologic diagnosis which may be made in studying sections from lymphomas when the possibility of

syphilis is not borne in mind. Moore calls attention to the increased tendency of Negroes to lymphoid reaction, including satellite bubo as compared with whites

Fig. 229.—A solitary gland of tuberculous origin. Note the tuberculid of the ear (moth-eaten ear) which identifies the process as tuberculous.

Fig. 230.—Tuberculous (not syphilitic) primary lesions in the temporal region, and cheek, A with its metastatic satellite lymph node. The satellite adenopathy of a tuberculous "chancre" may be found at a considerable distance from the inoculation site. On the genitalia, and about the mouth the syphilitic and the tuberculous chancre may so closely resemble each other as to be confused. As a rule the tuberculous chancre is much slower in developing and the apple-jelly tubercles often present can be recognized under glass pressure in the inflammatory areola, even though they may not be distinctly visible above. The tuberculous node tends to break down, the syphilitic satellite bubo does not.

The differential diagnosis of the satellite bubo in the groin is relatively of little importance to modern practice. It is impossible to distinguish chancre and chancroid by this means. Its absence in pseudochancre redux may be of

assistance in diagnosis, but it becomes highly significant in lesions about the head neck, extremities, and nipples About the head in particular it is usually unilateral (Fig 228) Vincent's angina in the throat may give rise to unilateral adenopathy often rather marked. But it is very much safer to investigate such cases thoroughly for syphilis than to fall into the very common interpretative errors represented by such cases as Fig 255

The adenopathy of inoculation tuberculosis is slower to develop (Figs. 230A, 231) more chronic, except in so-called "tuberculous chancre" or primary inoculation tuberculosis, usually marked by periadenitis and often associated with suppuration which is rare with the satellite

Fig 231—A tuberculous "pipestem lymphangitis" associated with a tuberculous primary lesion on the forearm and a satellite bubo in the axilla.

bubo (Fig. 231) If the lingual, tonsillar and pharyngeal lesions of the malignant lymphomas have an associated unilateral adenopathy it is much the safest course to investigate the possibility of syphilis by gland aspiration, Wassermann test, and complete examination, after prolonged observation, even though a pathologic study of these may have seemed to confirm the diagnosis of lymphoma. The possibility of gummatous adenitis must be borne in mind, though the condition resembles tuberculosis more than the satellite bubo (Fig 860)

Common Variations in the Chancre.—The chancre on the male genitalia assumes, more often than anywhere else the typical Hunterian form. On the glans there is nothing especially distinctive about its course, unless it develops at the meatus, in which case it may involve one or both lips, is usually of refractory type due to the irritation to which it is subject, and is said by

Fournier to run an especially chronic course which is hardly true under modern treatment Care must be taken not to pass too lightly over the edema of the *meatus often associated with gonorrhea, since this may be in fact an initial* lesion (see also Fig 219) The frequency of this association has been confirmed by the observations of Shropshear and Hibbs Palpation of the meatal as well as the urethral chancre should be in the long axis of the penis as well as transversely across the plaque The former manipulation may be the only means of detecting induration

Preputial Chancre.—The chancre of the anterior margin of the corona has no distinctive characteristics That of the posterior or preputial border of the corona, however (Fig 234) exhibits induration to the best possible effect. On retraction of the foreskin a saucer or boat-shaped cartilaginous plaque

Fig. 232.—A slightly scaling papule with faint induration—all there was to this patient's chancre Such lesions, if they attract the patient's attention at all, are interpreted as chafes, "hair cuts," etc. The induration is barely perceptible Such lesions may also follow the application of irritants to slight abrasions.

Fig. 233.—Massive induration of the frenum and glans penis in chancre at the sulcus coronarius.

suddenly flops back much as the tarsus of the upper eyelid flops back from the surface of the eyeball under the hand of a skilled ophthalmologist. We had always felt this particular "dory flop" induration to be almost as diagnostic as a positive darkfield until we encountered the case shown in Fig 235

Chancre of the frenum and of the lateral folds of the prepuce is especially apt to escape observation One of us (J H S) has seen the frenum all but amputated with the patient barely aware that anything was the matter The lesions are often small mere erosions, rather than indurated papules.

Phymotic Chancres.—The phymotic chancre is a not uncommon variety and is often confused with the balanoposthitis that may accompany a severe gonorrhea. It should always be painstakingly investigated for evidence of syphilis. Three types are recognized the doughy infiltration of the foreskin en masse nodular multiple infiltrates (Fig 233) and the rubber-ball type of

diffuse infiltration resulting in a firm ball-like enlargement of the prepuce and glans Not a few of these phymotic lesions are subjected to dorsal slit operations with risk of phagedena when a thorough examination of the discharge for spirochetes and the prompt institution of treatment would make such a mutilation unnecessary It is highly important in this type of lesion to avoid paraphymosis by attempted retraction of the foreskin in mild cases In the diffuse type and in cases with a chancre at the preputial edge cicatricial contraction of the opening in the foreskin may be marked and necessitate later circumcision when the process is healed

Fig 234 —Highly characteristic induration of the prepuce (double chancre). Compare Fig. 235. On drawing back the foreskin, this induration "flops back in almost diagnostic fashion.

Fig. 235 —Highly characteristic induration of the prepuce. This is not chancre but an induration produced by an infected sebaceous cyst. On aspiration pus as obtained, and pus as obtained from the enlarged inguinal nodes A complete follow-up demonstrated that the patient did not have syphilis. Note the "Fordyce disease of the glans (hypertrophied mucous glans).

Urethral Chancre.—The endourethral chancre is relatively rare, or at least seldom comes to clinical recognition.

The most recent studies indicat that the rarity is more apparent than real, and is due to the masquerade of this type of lesion under the symptomatology of gonorrhea and nonspecific urethritis. Friedman and Maner (1936) pointed out that in patients with gonorrhea but no penile lesions, persistent urethral discharge, examined by darkfield, may disclose an endourethral chancre. By special method for the darkfield examination of gonorrheal pus, Friedman (1939) identified *Sp. pallida* in the discharge of acute gonorrhea in 2 of 40 cases. Shropshear and Hibbs (1941) observed 10.7 per cent of primary and secondary syphilis in patients with gonorrhea, and 14.2 per cent of their patients with primary syphilis had coincident gonorrhea. In their series nearly one-third of the cases ith primary syphilis and coincident gonorrhea had intrameatal primary lesions A blood-tinged seropurulent discharge associated with redness and induration of the meatus or urethra with satellite adenopathy is, in their opinion, highly suspicious. Curley (1937) emphasizes the necessity for palpating the urethra in the male and examining the vagina,

cervix and urethra of the female for localized swelling with darkfield examination of the discharge Kemp and Shaw (1936) found that 26 4 per cent of 153 syphilitics in 1000 cases of acute gonorrhea had contracted their syphilis simultaneously with the gonorrheal infection. In every instance in which primary syphilis was present, it was diagnosable without dependence on the positive blood serologic tests. Army observers (Loveman and Morrow) emphasize the frequency of endourethral chancre in patients studied for gonorrhea who have coincident enlarged inguinal lymph nodes suspected of being lymphogranuloma venereum. Careful palpation will often disclose the site of the primary lesion, and darkfield examination of the lymph nodes reveals spirochets conforming to the type of the somewhat thickened organism which is within the range of morphologic variation for *Sp. pallida*.

It seems, also from general statistical estimates of the proportion of syphilitic infections which have presumably a masked onset (only a history of gonorrhea obtainable) that mild cases of seeming gonorrhea, and cases in which after a short acute course a thin serosanguineous discharge persists

Fig 226.—Very early epithelioma at the frenum, producing an erosion and slight induration, studded with minute translucent pearly nodules. Tuberculous lesions at the meatus may also occasionally be deceptive

would by a more systematic darkfielding and clinical study be shown to have their origin in urethral primary lesions. Certainly the 10 per cent of patients with syphilis who can give no history except that of gonorrhea represent a sufficiently large proportion to justify a Wassermann follow-up of every patient with gonorrhea and further study by darkfield if the gonorrhea runs an atypical mild course

The Genital Chancre in Women.—Genital lesions in women have been the subject of many conflicting statements due in part to the fact that in the casual management of patients they are both relatively inaccessible and therefore not seen and the victims of them are relatively uninitiated and uninquiring The problem of recognizing primary syphilis in the woman, therefore differs sharply and greatly to the detriment of the public health from that of identifying primary infection in the man The conflicting conceptions of the subject, dating back, many of them to predarkfield days have been thor

oughly modernized by the work of Gellhorn, Stookey and MacDonald in this country, and by the remarkable monograph of Anwyl-Davies from Great Britain which records and analyzes the largest existing experience. An extensive literature has recently been reviewed by Pariser (1941–1942) in connection with the *problems of the transmission of syphilis* by the woman. The conspicuous fact, brought forward by recent investigations, is the large proportion of primary infections which takes place on the cervix uteri.

Fournier's figures in 1906 reported 45.6 per cent of chancres in women on the labia majora and 22 per cent on the labia minora, with only 5.2 per cent on the cervix. The studies of Anwyl-Davies, however, show that the incidence of cervical chancres is 44 per cent in a series of 512 cases of primary syphilis, while the labia majora stand second with 31.3 per cent. Chancres of the labia minora, fourchette, urethra, and clitoris range from 8 to 2.7 per cent, and chancres of the vagina, vestibule, perineum, mons veneris and adjacent structures are among the rarities ranging from 1.4 to 3 per cent.

The morphology of the chancre in women varies markedly with the location of the lesion, and the lesions in general present variations on the erosive, the ulcerative, the papular and the indurative type, the induration being circumscribed or diffusely edematous. The differences between the primary lesions on the external genitalia in the man and the woman appear to have been overemphasized by the literature in the past, there being, apparently, few fundamental differences except those associated with distribution. Chancre of the clitoris is a comparative rarity in the woman, of course, in contrast to chancre of the penis. *Chancre of the urethral orifice, usually annular, is frequently mistaken for carcinoma.* Chancre of the vagina, on which Bille has collected the literature, is a rarity due, according to Pariser and others, to the low pH of the vagina and the lack of glandular openings. Syphilis d'emblée in women is an established fact, Anwyl-Davies reporting cases with a normal external os in which *Spirochaeta pallida* was obtained from the clear secretion from the canal. Pariser cites a number of observers, including Fuchs, Trost, Lesser, Puente and Gellhorn, who have identified *Sp. pallida* on the normal cervix after contact with infected individuals. It is also possible for *Sp. pallida* to be present on the cervix if a syphilitic primary lesion is present on the external genitalia, Gaucher recording a series of cases in which, if a primary lesion existed at all, it must have involved the endometrium. Warthin believed that nonformation of a chancre is particularly likely to occur where the organism penetrates a columnar-celled mucosa. In one case of primary syphilis of the endometrium he found that the perivascular infiltration had extended along the blood vessels, through the uterine wall, even into the broad ligament. Much too little attention is paid by the older observers to the confusion possibilities in the morphology of spirochetes present about the female genitalia particularly. This subject is adequately reviewed by Pariser. Further research will be necessary to establish the real significance of morphologic confusion of organisms obtained from the intact genital structures of women. In most instances where *Sp. pallida* indubitably is present, critical examination of the cervix will disclose an endocervical lesion or an involvement of the endometrium by a primary, secondary, or recurrent infectious process.

The Cervical Chancre.—The pseudorarity of the lesion is almost certainly the product of nonrecognition and of failure to use the speculum examination or to keep syphilis in mind as a possibility while making it. The cervical chancre is centrally placed, that is, surrounding the external os in 92 per cent

appears on the posterior lip in 17.5 per cent and on the anterior lip in only 9.5 per cent It is generally in the type encircling the os, somewhat larger than the male genital chancre but may vary from a large tumid induration to a mere macule, or in Anwyl Davies case to a pinhead-sized herpetiform vesicle

Th types of cervical chancre include the erosive, the ulcerative, and the diffuse indurative type which is relatively common and which has passed largely unrecognized except by Stookey and by Anwyl-Davies. Stookey also mentions the classical Hunterian lesion and two diphtheroid chancres. Anwyl-Davies, who has watched the development of the primary lesion following exposure in number of cases, states that the chancre begins as an erosion, generally single and central, surrounding or touching the external os at some points. The erosion is circular or oval, occasionally irregularly contoured, well defined, sharply circumscribed, regular in outline and with sloping edge. The ulcerative type, one third as common as the erosive, may extend to large fungating hypertrophic ulceration covering the whole cervical surface. Warthin believes that this type is the product of the invasion of the organism through squamous cell epithelium. Stookey believes that the diffuse indurative type is the most common chancre of the cervix, but Anwyl-Davies rates it as less frequent than the two previous types. Stookey and Polsky (1936) have called attention to what they describe as cold edema of the cervix, which is in reality diffuse indurative primary lesion without inflammatory or erosive characteristics. The size of the cervix is greatly increased and the consistency of the whole tissue assumes an India-rubber character elastic and indurated. N erosions or ulcerations can be detected and the diagnosis is confirmed by the presence of *Spirochaeta pallida* under darkfield examination in the secretions from the cervical canal. Simon (1938) states that the satellite bubo of the chancre of the internal genitalia in women can be palpated in the vaginal fornix over the external iliac vein

In the pregnant woman the primary lesion on account of increased vascularity of the pelvic tissues, is larger more conspicuous and generally indurated. On the cervix there may be extensive erosion and fissuring and a rigid, unyielding scar which interferes with dilatation of the cervix may result, a number of cases having been reported in the literature.

Malignant disease of the cervix is more frequently confused with chancre and gumma of the cervix than with any other disease The fugitive character of the syphilitic cervical primary lesion, formerly emphasized in the literature, has been discounted by Stookey and other observers and gynecologists no doubt see a number of chancres a year under the disguise of cervical erosions, vegetative lesions suggesting carcinomas, and the like The differential diagnosis of these lesions is extensively discussed by Anwyl Davies, to whose monograph reference should be made. Warthin was so impressed with synchronous carcinomatous and primary syphilitic involvement of the cervix that he insisted on biopsy even if *Sp pallida* was present.

The recognition of the primary lesion in the woman is then a matter of vigilance and routine search rather than of intrinsic difficulty Speculum examination should be made of the sexual partners of all male patients who are known to be in the infectious period of the disease The lack of routine speculum examination by an experienced observer accustomed to the tremendous range of variation of the primary lesion in women invalidates as statistical evidence some of the numerically large series in the literature In this way the inevitably high percentage of women who escape early recognition of their infections can be at least to some extent, reduced The very great importance of systematic examination of the cervix for all types of early syphilitic lesions has been clearly brought out by MacDonald who in an examination of 233 women found 91 with so-called "cervical erosions" with positive darkfields in 9 0 per cent, and 14 2 per cent who in addition had a positive Wassermann reaction with a negative darkfield. In their series of 233

erosions, 42.5 per cent of the lesions turned out to be syphilitic, in 60 per cent the diagnosis being established by the darkfield and 81.8 per cent by the positive serological test. It is evident, therefore, that darkfield equipment is as essential in the office of the gynecologist as in that of the syphilologist.

THE EXTRAGENITAL CHANCRE

The primary lesion of syphilis when it develops on other parts of the body than the genitalia, is protected from recognition by a singularly low threshold of suspicion on the part of physicians. A lesion on the genitalia may arouse some suspicion *a priori* but a lesion on the finger the lip, or the tonsil seldom does Syphilis seems to be suggested last to the examiner instead of first of all the existing possibilities. As long as this state of mind exists the recognition and proper appraisal of extragenital onset in this disease will be anything but complete.

Chancre of the Lip.—The overwhelming proportion of extragenital lesions occur about the mouth, as might be expected when the popularity of mouth to-mouth contacts and the predilection of infectious lesions for this site is considered

In Bulkley' monumental compilation, 20 per cent of extragenital chancres occur upon the lip, probably due to the fact that the literature he reviewed emphasized other rarer types of lesions. In his private cases 65 per cent occurred about the mouth. Fournier found 75 per cent occurring about the head, and of these, 66 per cent upon the lips. Cole (1916) found 77 per cent of the extragenital lesions observed by him occurring on the lips. Tobias (1936) found the proportion on the upper as compared with the lower lip, as 20 is to 16. Wile and Holman (1941) found 46 per cent lip, 10 per cent tonsil, 6 per cent finger 5 per cent tongue, 2 per cent breast, 2 per cent pharynx, 1.5 per cent each of forehead, chin and arm.

Extragenital Infection in Children.—Waugh (1936) in small series between five months and eleven years of age, found only tw who had acquired syphilis through definite sexual contact. Smith (1930) pointed out the relatively small number reported of many cases collectable, the preponderance of females, the importance of household contacts, the importance of sporadic family epidemics in which an adult or older child, acquiring the infection by sexual exposure, transmits it extragenitally to others. Sleeping with person ith secondary syphilis was the means of transmission in eight cases. Extragenital chancres are frequent, 90 per cent of them occurring about the face and neck. Smith identified also cases of transfusion syphilis alone in his series. Applebaum (1937) reports chancre of the upper eyelid in an infant two months of age which he believes to have been acquired from the birth canal of the mother who had late secondary syphilis

Kissing.—This constitutes apparently the overwhelmingly predominant mode of transmitting the disease extragenitally Chancres from genitobuccal contact are comparatively rare, so that the real danger lies in the ordinary osculatory salute and the "baiser d'amour " There are few things more dangerous than being kissed by a syphilitic, and all patients with the disease should be strictly and specifically enjoined against the practice.

Certain occupations have in the past been subject to special risks of mediate mouth transmission and epidemics of syphilis among glassblowers, for example, have occurred. The common drinking cup in a gang of men may be a prolific source of infection and the same principle applies to all utensils and tools which may convey material from the infected mouth to suitable sites on the body of the victim. Droplet material from coughing or spitting is a real danger likewise. The chancre of the lip that follows the familiarities of an engagement in which either party but more often the man, has active lesions in the mouth is more common than is realized.

The surprising turn which such infections may tak is suggested by Shaffner' report of chancre of the eyelid in woman following a daughter ttempt to remove a foreign body from the mother eye with her tongue In Schamberg famous case 7 young women developed primary lesions of syphilis following kissing game in which a young man participant had hancre of the lip. Another young man was subsequently infected by kissing one of the infected girls.

C

Fig 237 —Chancre of the upper and lower lip, and epithelioma of the lower lip in young man of twenty-six A, with chancre of the upper l p as brought to the clinic to have the tumor excised. B shows the edematous border of chancre which may sometimes suggest malignancy C shows the rough base rugged edge nd "pearling of the border in an epithelioma.

Differential Diagnosis of Lip Chancre.—Chancre of the lip should therefore on account of its frequency form part of the routine mental differentiation applied to every lesion of the lip at its first examination (Fig. 237) It is as true of chancre of the lip as of the primary sore upon the genitalia, that every single *one of the criteria of purely physical diagnosis may fail to identify the lesion*

as syphilitic. For this reason the attitude of mind that a lesion upon the lip is a chancre until it is proved otherwise is the safest from the standpoint of the recognition of syphilis, though too sweeping for general acceptance. Certainly any lesion which presents the group of three characteristics mentioned as still surviving the critique of darkfield study should arouse suspicion. A lesion which is indurated slow to develop and heal, and associated with a marked satellite adenopathy is a chancre until it is proved otherwise

Differentiation of Chancre and Carcinoma About the Mouth.—This pronouncement brings us face to face with a possibility more frequent and serious about the mouth than upon the genitalia Squamous cell epithelioma (Fig. 238) developing upon normal mucous membrane, upon a previous leukoplakial patch or upon an actual gumma may simulate chancre to the minutest detail Delay in the diagnosis of epithelioma of the high grade of malignancy usually encountered about the mouth and lip is more serious than delay in the diag-

Fig. 238.—Epithelioma of the lip in patient with positive blood Wassermann reaction and cutis marmorata that was confused with secondary eruption. Note the easy bleeding of the lesion and the leukoplakia at the left commissure. There is satellite bubo (malignant) below the ramus of the jaw to complete the resemblance to chancre (see text)

nosis of a chancre in the same situation For that reason it is unpardonable to use time-consuming procedures like the serologic follow up as the sole resort in the differentiation of malignancy about the mouth from chancre A diagnosis can however be clinched forthwith by the procedure employed in Fig 238

In this case darkfield examination of the lesion was made first. A Wassermann examination taken at the same time was positive The darkfield was negative as might be expected in late chancre, and the Wassermann on repetition was again positive. Even this combination of evidence does not prove the patient to have chancre. Treatment was at once instituted and three arsphenamine injections in five days failed materially to alter the appearance of the lesion. A piece of tissue was then removed for frozen section diagnosis, with the patient prepared for operation, and report of squamous cell epithelioma returned

The correct diagnosis had however been predicted from a single detail of examination which assists in raising a suspicion of malignancy about the lip The typical chancre of the lip bleeds very little even on rather rough

handling The epithelioma, on the other hand usually bleeds on the slightest touch The slight distortion of the lip in photographing the lesion in question (Fig 238) resulted in pronounced bleeding The pearly border of epithelioma, composed of hard slightly translucent nodules each with its little rim of dilated capillaries visible under the lens, is of material assistance in identifying many malignant lesions. It is not, however invariably present and, as shown in Fig 237 B an inflammatory flange-like edge on a chancre may give a momentarily false impression If the suspicion of epithelioma is strong as little manipulation as possible should be employed in studying the lesion and serum for darkfield examination should be collected without scraping or squeezing It may be preferable in reaching a diagnosis to perform a biopsy first and examine the shaving of tissue by frozen section with the patient prepared for operation in order that no dissemination of the carcinoma may result if the pathologic findings are positive.

Cole in his study of the extragenital lesion directs attention to the value of the inflammatory quality of the chancre in differentiating it from other lesions about the lip This is especially useful in leading to the fuller investi-

Fig. 239 —A gumma of the upper lip simulating chancre, but treated for some time with silver nitrat On involution under treatment for syphilis scarcely scar was left.

gation of supposed epithelioma which is relatively noninflammatory It is not, of course proposed as an absolute criterion.

Wile and Holman (1941) observed the healing of chancre under radium (which might further the confusion with carcinoma) and have seen treatment-resistant primary lesion finally healed by roentgen-ray (Beerman, Ingraham and Parker 1943, case of Hough a.)

Further Differential Diagnosis of Lip Lesions.—The further objective differentiation of lesions on the lip includes gumma, pseudochancre redux, inoculation tuberculosis, sarcoid vegetative dermatitis pyogenic granuloma chancroid blastomycosis, and sporotrichosis.

Gumma (Fig 239) is usually identified by the slower course, absence of satellite adenopathy and negative darkfield examination. The histopathologic findings and Wassermann, of course may not be distinctive (see Chapter I). Pseudochancre redux is identified by the same criteria. Inoculation tuberculosis rarely occurs on the lip, although this may be the origin of so-called "tuberculosis orificialis faciei, from secondary involvement of the throat and nasopharynx. The apple-jelly nodule small, translucent, brownish tubercle recognized on blanching the erythematous surface by glass pressure is usually easily identified. The satellite adenopathy of inoculation lesions usually suppurates early and tubercle bacilli can often be found in the discharge (Fig 240). Sarcoids, rarely seen about the lip, but often around the nose and cheek, are tumors or plaques,

of tuberculoid histologic architecture which practically never ulcerate or erode. They are negative to all examinations for syphilis, but may respond to arsphenamine treatment, though not so readily as syphilis. Vegetative dermatitis usually presents the mammillated surface and pus crypts of the pyogenic granuloma, but may at times, on the lip, form the sessile or pedicled dark red, easily bleeding tumor now known to be merely a highly vascular granuloma of pyogenic origin. These lesions are negative to darkfield and other examinations for syphilis and clinically are not very suggestive. Chancroid of the lip is excessively rare and presents the same general features as on the genitalia. The earmark of blastomycosis, which is also rare on the upper lip, is the extending papillomatous border with central contractile scar and the minute epithelial abscess, found between the papillomatous projections of the margin. On pressure with a ring curet over the margin several minute droplets of pus can usually be made to exude. In this pus the blastomycete may be found, a typical yeast with double refractile wall and budding forms. The diagnosis should not be attempted by the inexperienced on microscopical grounds alone. Sporotrichosis of the upper lip produces a small pustule which extends, giving rise to early metastasis to adjacent lymph nodes and the skin along the connecting lymphatic channel. It is well to take cultures on lesions of the lip if they are infected or ulcerated. Maltose agar and room temperature are necessary for the growth of sporothrix.

Fig. 240.—Fissured chancre at the labial commissure, with submaxillary adenopathy.

On one occasion an infected hemolymphangiomatous nodule produced a picture on the upper lip requiring differentiation from chancre. A cluster of minute lymphangiomatous vesicles could be recognized on the border. The tularemic "chancre" may too, as presently discussed for the finger, conceivably require differentiation on or near the lip.

Herpes of the lip deserves special mention in differentiation because while the cluster of vesicles with their polycyclic or scalloped confluent borders and superficial crusting is generally easily recognized, herpes is the commonest misdiagnosis of early chancre of the lip. A herpes which requires more than two weeks for its involution is suspect, especially if any signs of associated unilateral adenopathy have appeared. A more determined policy with reference to the darkfield search of such lesions would doubtless result in many negative findings, but would arrest at its onset many a tragic case of extragenital syphilis, especially in the young fiancée.

Oral and Pharyngeal Chancres.—The chancre within the mouth and pharynx is much less common than upon the lips according to the Fournier

statistics (3 lip to 1 mouth chancre) Here again a wide range of variability is possible, while the difficulties of exact laboratory diagnosis are unfortunately markedly increased by the unreliability of darkfield findings in the mouth and throat. An inconspicuous type of chancre of the tongue is the smooth eroded plaque whose induration is best apparent on palpation (Fig 241) and which is almost devoid of subjective symptoms The ulcerative type described by Fournier is much less common

Tw rare types, the fissured chancre and the diffuse plastic infiltration, are also described. The former is t times difficult of distinction from the fissured tuberculous lesion of the tongue, and the latter may be confused with diffuse gummatous infiltration and epithelioma. W have seen tuberculosis, with the bacilli present in the lesion nd in the sputum, mimic almost perfectly the fissured and the eroded plaque types of chancre of the tongue. The discovery of signs of pulmonary tuberculosis t first examination, and smear stained by the Ziehl-Neelsen technic usually identifies the tuberculous element, but should not discourage full investigation for the possibility of syphilis Clinical identification of t berculosis does not exclude the possibility of syphilis.

Fig 241 —Chancre of the tongue, showing merely slight erosion. The induration, however as pronounced. On deep aspiration of the base the *Spirochaeta pallida* was obtained

Chancre of the gum is regarded as a rarity and in all probability this rarity is genuine and not the product of lack of recognition.

The simple erosive type ill probably arouse suspicion of itself but the diffuse form, described by Fournier *alveolodental periostitis, of which Fig 260 was perhaps an example* is probably seldom identified as such. Klauder has described case with study of the literature.
Through the courtesy of Professor Wile, one of us (J. H. S.) has also had the opportunity to see gingivitis involving the right side of the lower jaw from which *Spirochaeta microdentium* was obtained in almost pure culture The organism in darkfield is difficult to distinguish at times from *Spirochaeta pallida* and might have produced deceptive impression of early chancre of the gum.

Chancre of the Tonsil.—The tonsillar chancre is, in our opinion the most neglected from the standpoint of early diagnosis of all the buccopharyngeal primary lesions Morton Smith has hazarded the opinion that it is really very common, and there can be no doubt that it frequently masquerades as diphtheria Vincent's angina, carcinoma and lymphosarcoma of the tonsil While bubo is known to be a feature of Vincent's angina, there can be no question that such cases deserve painstaking study for syphilis and an appropriate

follow-up and observation instead of the local treatment followed by tonsillectomy and dismissal which is too often the rule.

Simple chancre of the tonsil is almost invariably *unilateral*, and appears as a firm, slightly elevated plaque, at times with surprisingly little involvement of the peritonsillar tissues. The surface covered with a grayish exudate, is at times difficult to distinguish from the tonsillar mucous patch. The degree of induration is very variable and according to Fournier may be altogether absent. The detection of the induration is made difficult by the inaccessibility of the lesion, but with practice the tonsil can be propped against the posterior pillar with a flat wooden tongue blade and the degree of induration tested by pressing the base of the tonsil with the end of the blade.

Crateriform ulceration of the tonsillar chancre may occur and, with the induration and eversion of the border may simulate carcinoma. The age of the patient while suggestive does not by any means settle the question now that a more trustworthy criterion is available in laboratory diagnosis.

Differential Diagnosis of Tonsillar Chancre.—Diphtheria, Vincent's angina, and lymphosarcoma are the most difficult lesions to differentiate from chancre of the tonsil. Clinically the chancre may simulate even the adherent membrane of diphtheria and the gangrenous extensions on to the pillars and palate with associated lymph node enlargement seen in Vincent's angina.

The identification of Vincent symbiosis of large spirilla and fusiform bacilli in smears does not by any means prove the condition to be an uncomplicated Vincent's angina. Many ulcerative mouth lesions, including both undoubted malignancy and undoubted syphilis, may be contaminated with the Vincent organism. H. L. Lillie has expressed himself as believing that Vincent's angina is not an entity and that the saprophytic picture which it represents may complicate streptococcus infections and a variety of ulcerative lesions in the throat.

Darkfield Diagnosis.—Mahoney and Bryant (1934) pointed out that even expert observers did not agree on the differentiation with respect to *Sp. pallida*, of certain oral (tonsillar) spirochetes. In 40 per cent of tonsils examined confusion was possible.

Constitutional Symptoms Deceptive.—The constitutional symptoms accompanying marked infections of the tonsils do not always eliminate chancre from the diagnosis, for saprophytic or secondary infection of a syphilitic primary lesion may easily give rise to incidental symptoms of malaise, local pain, arthritides, and arthralgias, loss of weight, and other symptoms of systemic reaction. Such constitutional symptoms are moreover not uncommon in the preeruptive or secondary incubation period of syphilis with an uncomplicated primary lesion. Thus, although entirely legitimate accompaniments of a chancre in the throat, the constitutional symptoms may create the impression that the lesion is due to some other type of infection and deflect attention from the true state of affairs.

Satellite Adenopathy in Lip and Mouth Chancres.—Satellite bubo in lesions about the lip and buccopharyngeal cavity usually involves the submental and anterior cervical groups of nodes as has been stated and apart from somewhat greater conspicuousness, a *strict unilateral character* and solitary tendency presents the usual features of the satellite adenopathy of the chancre elsewhere on the body. The easy accessibility of this bubo to darkfield study by node aspiration, which eliminates errors due to contaminating mouth organisms is of material assistance in the diagnosis of lesions within the throat. Systematic study of such localized adenopathies associated with throat lesions should yield a very fair return in extragenital chancres which would not otherwise be diagnosed until the appearance of secondaries, or

which would because of inadequate general examination, be overlooked entirely until in later life the patient appears with other evidence of syphilis. The confusion of massive satellite lymphadenopathy with lymphosarcoma is emphasized by several case histories in this text. Clodfelter (1936) reports a case in which a syphilitic primary bubo was diagnosed as Hodgkin s disease by clinicians and a competent pathologist with recovery under anti-syphilitic treatment.

Chancre of the Nasal Septum—This rare type usually observed in physicians, is seldom diagnosed.

Chancres of the Finger and Hand.—Of the remaining types of extragenital chancres, those involving the finger and hand deserve special mention because early diagnosis of such lesions is all but unknown owing to the low threshold of suspicion regarding them. Medical men themselves, and those associated with them in the care of the sick, are the most frequent victims.

Fig. 242.—Chancre of the index finger in physician who, following the advice of several colleagues, came t have his finger amputated for sarcoma. *The Spirochaeta pallida was bundant,* the blood Wassermann reaction positive, but no secondaries had appeared. There was febrile therapeutic shock following the first arsphenamine injection.

Fournier states that of 49 chancres of the hand hich he had seen, 30 ere in physicians, and that the infection as most often the result of manipulations involving the genitalia both in diagnosis and operative ork and in digital explorations of the mouth cavity This statement holds good today Obstetrical procedures, dental manipulations nd bare-handed tonsillectomy are defini sources of danger Wile and Holman (1941) observed chancre of the palm in physician who arrived t an obstetrical delivery in time to exert bare-handed pressure on the presenting head. Among laymen digital chancres from genital contact hile not common seem t escape diagnosis consistently and the bru l chancre of the knuckle from inoculation following blow on the mouth of syphilitic is seldom identified short of the ppearance of secondary lesions, if then

It is highly important to bear in mind certain points about the chancre of the finger While an abrasion or hangnail is a common starting point, it is not a necessary one Actual solution of continuity is not necessary The clinical appearance of the lesion exhibits the widest variability Erosion or ulceration may not occur and the lesion may present no more than the appearance of a mild paronychia At the other extreme the digital chancre of the tip of the finger may develop into a beefy-red granulating, fungous lesion which seems to suggest sarcoma (Fig 242) more often than any other clinical diagnosis

This lesion, like the felon chancre, may be intensely painful, a fact which has been responsible for many errors in diagnosis The physician s suspicions are set at rest because he has been taught that the typical chancre is painless The felon chancre as its name indicates is a painful bulbous enlargement of

Fig. 243 —"Felon chancre" in hospital attendant. The lesion healed after two incisions for supposed whitlow The patient then appeared with secondary syphilid.

the tip of the finger which seldom escapes without at least one incision (Fig 243) in the effort to evacuate pus that may or may not materialize. The finger may serve as the point of inoculation for syphilis without the development of any local reaction whatever The 4 cases which withstood Almkvist s critique

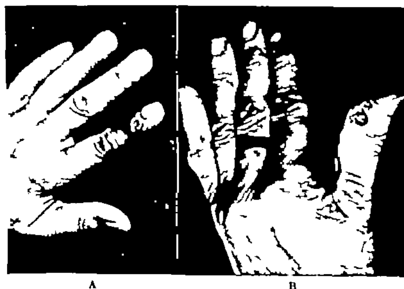

Fig. 244 —Tularemic chancres of the fingers. They are accompanied by satellite adenopathy (Courtesy of Dr C. N Kavanaugh.)

of reported instances of syphilis d emblée were all needle-prick inoculations. Operating upon untreated and especially early syphilitic patients is therefore a particularly risky procedure for needle prick inoculation is the one definitely established method in man of acquiring syphilis without even the warning

of a chancre Darkfield examination of a suspected digital chancre especially within the first two weeks of its course yields excellent returns in early diagnosis We feel no hesitation in saying that it should be an absolute rule among medical men to have darkfield examination of any lesion about the finger even though trivial, which does not heal within this period Those who make barehanded vaginal examinations and operate without gloves should be particularly alert in this matter This applies especially to gynecologists and otolaryngologists.

Fig. 245

DIFFERENTIAL CONSIDERATIONS IN "PHYSICIAN'S CHANCRE"
(The Chancre of the Finger and Hand)

1 Simple infection—more acute and inflammatory; more rapidly progressive (hours or days rather than days or weeks); visible, early lymphangitis (?) softening of the gland fever and septic symptoms. Pain is not of differential value. Darkfield negative, BWR negative unless intercurrent syphilis.
2. Inoculation tuberculosis—indolent or chronic, lymphangitis delayed, noninflammatory, cordlike gland may follow partial healing of lesion; softening or adherence of gland apple-jelly nodules in periphery of primary (Fig 230 A) Darkfield negative, BWR negative, unless intercurrent syphilis.
3. Sarcoma—including melanotic whitlow—slow development, late adenopathy pigment deposits or bone changes. Darkfield negative, BWR negative unless coincident syphilis.
4. Epithelioma—keratoses often present, rolled border ready bleeding late adenopathy delayed course.
5 Tularemia—adenopathy first and painful only later (twenty-four hours) A painful, swollen, inflamed papule, breaking down with necrotic core, punched-out ulcer with raised margin, healing with scar Darkfield negative. Lymph nodes suppurate and discharge Subcutaneous nodules suggest sporotrichosis. Chills and fever
6 Sporotrichosis—nodule, early suppuration, subcutaneous softening nodules along lymphatic chain; early suppurative lymph nodes darkfield negative, positive culture
7 Rat-bite fever—history of bite, ready healing, twelve to thirty day incubation, pain, swelling, lymphangitis, visible red streaks usually preceded by chills, fever May ulcerate.
8. Anthrax —angry inflammatory papule or papulopustule, developing dark or black necrotic center early fever, palpable, tender satellite lymph nodes, local spread.
9 Foreign body reaction—tender papule mildly inflammatory No erosion, sticking pain pressure, no adenopathy
10 Erysipeloid—history of fish, crab, or meat handling vesicopustule inflammatory healing and followed by migratory erythema as high wrist local tender adenopathy

MAKE A DARKFIELD EXAMINATION OF EVERY INDOLENT LESION OF HAND OR FINGER ASSOCIATED WITH LOCAL ADENOPATHY

The satellite bubo of the chancre of the finger or hand is usually the swollen epitrochlear node. At times however the reaction takes place in the axillary group where it may be overlooked unless a search is made for it. We have seen the node excised and incised as tuberculous

The differential possibilities are summarized in Fig 245 and include simple infection, felon, inoculation tuberculosis, sarcoma epithelioma tularemia, sporotrichosis, rat bite fever anthrax foreign body reaction erysipeloid

Chancre of the Eyelid.—Chancre of the eyelid (Fig 246) deserves mention among the types of onset of syphilitic infection among medical men Two of four such lesions which Stokes saw were in physicians and in none did the ophthalmologist consulted make or even suggest the diagnosis. In both cases the higher threshold of suspicion of a syphilologist, and an appeal to the ever

ready darkfield established the nature of the condition. Droplet infection from coughing patients and transfer of material to the eye by a careless gesture are the principal modes of inoculation.

Chancre of the Nipple.—Of chancres of the remainder of the body the nipples are conspicuous sites in women but are rarely involved in men. With

Fig. 246.—Chancre of the lower eyelid in physician. Thought to be exogenous infection. *Spirochaeta pallida* demonstrated by darkfield.

the application of the Wassermann test to wet nurses, and a better comprehension of the standards of examination appropriate in such cases the nursing chancre has become much less common. The principles laid down for detection of this type of primary lesion granted a proper degree of alertness in the physician do not differ in any particular from those applicable to other types of primary lesion.

Fig. 247.—Chancre of the neck, treated for two weeks as "furuncle." Note the ecthymatous ulcerative character of the chancre on the skin. The bubo lies immediately beneath and posterior to the lesion. The patient secondary eruption, mild macular syphilid, unrecognized, is shown in Fig. 261. It is not wise to diagnose, dress, or treat chronic lesions of the skin without completely examining the body surface. The *Spirochaeta pallida* was found in small numbers in this lesion.

Chancres on the Skin.—It should be borne in mind in general that the appearance of a chancre on the skin of the body is usually markedly different from that of the lesion on mucous and mucocutaneous surfaces (Fig. 247). The chancre of the skin is more apt to be crusted and ecthymatous in appearance does not present the definite circumscribed induration of the base found in looser and thinner tissues, and on removal of the crust is often found to be an ulcer with a raised margin rather than an erosion. The recognition of such lesions in the first few days of their course is more than can reasonably be

expected of the average physician If however the criteria of chronicity and satellite adenopathy be recalled, an alert observer will usually find his suspicions aroused by the evolution of the lesion within the first two or three weeks

Anorectal Chancre.—The anal chancre resulting usually from pederasty varies considerably in morphology A typical Hunterian primary lesion may

Fig 248.—Anthrax pustule (shaving brush infection) with satellite bubo. The ring of rapidly spreading edema with central gangrene is distinctive. Lesion five days old.

be present at the external ring or on the adjacent skin. Occasionally a hemorrhoid may be transformed into an indurated primary lesion. Diffuse brawny infiltration of all or part of the external or internal ring may occur and multiple fissured chancres may also develop Ault (1937) in a critical review states

Fig. 249 —The distinctive rolled pearly border of solitary basal cell epithelioma of the hand

that the anal chancre most commonly resembles posterior fissure and begins as a clean ulcer with a ragged edge and subsequent secondary infection.

Case Histories of Extragenital Lesions.—The following case histories illustrate more vividly than any purely descriptive presentation the unexpected onset and the ineffectiveness of incomplete precaution in preventing infection with syphilis Two of the cases illustrating the gynecological and

otolaryngological chancres, so to speak, are rendered in dialogue almost literally as they occurred

Case History.—A young man was sent for examination after four weeks of treatment had failed to heal an indurated paronychial lesion on the outer aspect of the nail bed of the right middle finger Although college student, the patient orked during spare time in garage and gave history of having bruised the finger slightly at the site of the lesion while cranking a car

Fig 450.

THE EXTRAGENITAL CHANCRE IN THE PHYSICIAN

Three Doctors, Three Students, Three Weeks

Doctor No. 1.

12/10/31 Nicked thumb with glass ampule fragment in barehanded obstetrical delivery
12/20/31 "Infection. Incised. Hot wet dressings. -Ray picture. Blood Wassermann reaction negative. Other chemistry negative.
Right axillary denopathy
3/3/32 General rash.
Diagnosis "Septic eruption.
3/25/32 Neo 0 3 Gm. given for "Vincent infection of mouth (not for syphilis).
3/26/32 On insistence of son (M. D.) Kahn test done, reported 4 plus.
3/28/32: Treatment begun.

Doctor No. 2.

2/11/32: Sore, right index finger noted.
Had done barehanded tonsillectomies and local treatment on 3 syphilitic throats.
3/10/32 Axillary adenopathy
Node excised.
3/15/32 Fever malaise, rash.
Diagnosed chickenpox.
3/24/32 BWR strongly positive.
3/25–29/32 Three injections neoarsphenamine with explosive reactions. "Given Pho-eti—like hypodermic, doctor
3/31/32 Sent for advice as to "intolerance

Doctor No. 3.

3/10/32 Did barehanded circumcision on patient with gonorrhea, later discovered to have condylomas ed ani and BWR positive.
4/2/32 Finger sore.
4/3/32 Darkfield negative. BWR negative. Five darkfields & BWR negative since.
4/15/32 Darkfield positive. Axillary adenopathy
4/16/32: Darkfield again positive, 3–4 pallida per HP field. Kolmer Kahn, Kline tests negative.
4/16/32 Treatment begun.

Comment

1. Seven doctors participated in this three weeks of tragedy as observed in my office. Three of them are former students of mine, two of whom figured on the right, one on the wrong side of the diagnosis.
2. All the three victims were caught by technical slips that sooner or later lead to trouble
   (a) Barehanded operating on throat and genitals.
   (b) Operating on patients with active syphilis not recognized.
   (c) Operating on early syphilitic patients not sterilized (one dose of "914") before operation.
3. One victim had repeatedly exposed his wife.
4. Only one (No. 3) followed the proper course after sore appeared, and began treatment while seronegative. He was urologist.
5. The other two illustrate most of the blunders that can be made in diagnosis and treatment.
6. The "index of suspicion makes the diagnosis of syphilis. "How shall the blind lead the blind?"

"PHYSICIAN HEAL THYSELF"

The lesion was therefore interpreted as banal infection. When seen by the syphilologist the satellite bubo and positive darkfield on aspiration established the lesion as chancre. He was then more closely questioned as to his activities, and admitted exposure the evening of the accident in cranking the car. He disavowed titillation, pparently truthfully but recalled having used the second and third fingers of the right hand to separat the labia. Following the exposure he took vigorous genital prophylaxis, but forgot to include the finger upon which his chancre subsequently developed. W have seen chancres develop simultaneously on both penis and finger under similar circumstances without prophylaxis.

Case History—A young man presented himself in the clinic complaining of pain on defecation. A proctoscopic examination, while only partly successful because of the excruciating pain, revealed some redness of the mucocutaneous junction about the external ring but no ulceration. There was palpable doughy infiltration, exquisitely tender. A Wassermann test was strongly positive and the patient was thereupon sent to the dermatologist, who found him to be in the florid eruptive secondary stage of syphilis without any visible sign of primary lesion. The personality of the patient was not such that an anal chancre from pederasty seemed possible. The patient was urged to remember as closely as possible the circumstances of his recent sexual experiences. Following successive exposures at about the proper interval before the appearance of the lesion, he had gone at once to a medical friend who had supervised a thorough genital prophylaxis. While the details could not be corroborated by confrontation, it appeared highly probable that he had developed an anal chancre from mediate transference of the virus to the anal ring by the partner's finger, his prophylaxis having protected him from a genital lesion. We have seen similar mediate transference in a case of chancre of the abdomen in which the penis itself escaped apparently as a result of prophylaxis, although acting as the transmitting agent before prophylaxis was applied.

Case History—A gynecological surgeon stopped me on a street corner about some trivial matter. As we conversed, he rubbed his right index finger.

"What is that?" I asked.

"A little infection, I guess," he replied.

The finger presented a very slightly reddened, slightly raised swelling along the nail margin—no erosion, no ulceration—scarcely a lesion of any sort, in fact.

"Come on out with me and I'll darkfield it."

"Oh shucks, it's nothing. Getting better too."

"Better have it darkfielded anyhow. Little things like that in gynecological men are apt to be serious."

"Never mind, there's nothing to it."

This was the last I heard of it for the time. A year and a half later I was told by the physician who had treated him that he had developed secondaries. He wanted me to know of it because I had made his diagnosis on a street corner. At no time had the primary lesion on the finger deserved the name of chancre.

Case History—Two surgeons were arguing with an otolaryngologist in the opposite sleeping car section.

"Let me drill a hole in that nail. I'll bet you there's pus under it."

The otolaryngologist had a slightly raised paronychial lesion of a week's duration about the nail of the right index finger with some blueness of the nail bed. He consented reluctantly and, after sterilizing the blade of a pocket knife with a match flame, one of the surgeons drilled a hole through the nail. To the disappointment of all, no pus appeared. In the meanwhile I had inspected the lesion from the arm of the seat, and at a distance of 4 feet had felt the "hunch" of intuitive syphilological diagnosis.

"I'll give that 90 per cent for a chancre," I ventured.

I received the visual signs of incredulity from all present.

"You do nose and throat, don't you, Doctor?" I proceeded boldly.

"Yes."

"And strip the capsule with your finger?"

"Yes, I got that technic at the X—— Hospital."

"Whom did you operate on a month ago, can you recall?" I asked.

"By Jove that's right—we took a Wassermann later when her throat didn't heal and found it was positive."

"There you are," I finished. "As soon as you get to M—— I want you to go to Y—— and get him to do a darkfield on that finger instanter and, if it is positive, begin treatment."

"Nothing to it," was the nose and throat man's verdict.

I appealed to one of the surgeons, who promised to back my instructions with force if necessary. Four days later I was passing through a hotel corridor when the surgeon who had drilled the nail came up to me and spoke sharply in my ear the words "Teeming with spirochetes."

CHANCROID, LYMPHOGRANULOMA VENEREUM, GRANULOMA INGUINALE

Because of the frequency with which the diagnosis of syphilis is entangled with certain other venereal diseases, a brief working description, by no means complete, is offered to round out the presentation of the primary syphilitic lesions.

Chancroid.—In syphilologic perspective the diagnosis of chancroid has a negative rather

than positive significance. So long as morphologic criteria held the center of the stage chancroid provided a pitfall for the unsuspicious and inexperienced diagnostic mind or for those who instinctively tend to avoid a diagnosis of syphilis as long as possible. This was quite apparent in the experience of the American Expeditionary Force during World War I in which the tendency of men without special venereologic experience to diagnose chancroid in genital lesions, which ultimately proved to be double infections, was a serious breech in the diagnostic ramparts. Chancroid is a local ulcerative process (in rare instances, Milian has insisted that there may be systemic complications) whose syphilologic importance consists in the fact that it may simultaneously be the site of development of a primary lesion of syphilis.

Admirable monographic presentations of chancroid as such have been published by Maurice Sullivan (1940) and many valuable investigations by the Cleveland City Hospital group headed by Cole. Major Greenwald's (1943) summary well presents the army problems and methods.

Chancroid, ulcus molle or soft chancre, is an acute localized autoinoculable venereal disease caused by the streptobacillus of Ducrey (*Hemophilus ducreyi*). The local genital lesion is a non-indurated tender ulcer with an incubation period averaging three or four days, but as long as twelve or even twenty-two or more days (Greenwald). The ulcers are irregular, present a granular dirty grayish base covered with a small amount of grayish purulent exudate and with slight undermining at the edges. Free bleeding follows manipulation. The ulcers are more frequently multiple than single and tend, because of their autoinoculability, to become more numerous the longer the course of the disease. The commonest location is at the edge of the phimotic prepuce or in circumcised males, on the frenum and in the coronal sulcus. Fifty-four per cent of Greenwald's patients presented involvement of the inguinal lymph nodes on reporting. Pain is common in the more advanced stages, and is occasionally attended with fever and anorexia.

Venereologically it is interesting that chancroid is much more frequent in men than women, although it is believed that women may be asymptomatic carriers of the *Hemophilus ducreyi*, and it has even been suggested by Brams (1944) that this organism may be found in some males as a saprophyte in the smegma of the coronal sulcus. The incidence in Army practice, as between Negroes and whites was, in Greenwald's experience in a ratio of 120 : 1—a disproportion which does not appear in the incidence of gonorrhea or syphilis. Chancroid is notably more resistant to prophylactic measures than the other venereal infections (Greenwald) and according to this observer soap and water particularly advocated for prophylaxis, is not effective.

The most annoying complication of chancroid, the suppurating bubo, is usually unilateral with matting or fusion of the enlarged glands after a lapse of time, the development of fluctuation, and unilateral suppuration following. Spontaneous healing or extensive ulceration may follow such spontaneous rupture. Ravechkolb, particularly studying the factors leading to the development of bubo, formulated the following axioms with regard to it (1930).

"The smaller and more inaccessible the ulcers are to therapy the more likely the occurrence of buboes.

"Conversely the larger and more accessible to therapy the lesions are, the less the incidence of buboes.

Caustics or actual cautery predispose to the development of adenitis.

"Lesions so situated as to produce phimosis and poor external drainage are more apt to initiate adenitis than are lesions on the cutaneous surface of the prepuce or the shaft of the penis.

Induration is not ordinarily a characteristic of the chancroid in the male or female, except as the result of cautery or irritant treatment, and its spontaneous appearance should always arouse suspicion of a double infection with syphilis.

The diagnosis of chancroid as well as its treatment has been materially advanced in recent years. The smear, with identification of the organism by a Gram stain, Wright stain, or methyl green pyronine is now so satisfactory in competent hands that Kornblith, Jacoby and Chargin (1941) rated its efficiency at 89 per cent, and Greenwald at 65 per cent. The "school-of-fish-like" arrangement of the organisms among the leukocytes of the smear is rated as specially characteristic. The complement fixation tests have been rated as unreliable, but the Ito-Reenstierna intradermal tests have a high degree of specificity and, like the tuberculin test, have great negative as well as positive significance, because permanent skin sensitization for the antigen apparently results from an attack of chancroid at any time in life. The time required for the test to become positive, which is important in early diagnosis, is rated by Speiser (1944) as low as six to ten days, and by Becker and Obermayer (1940) at a minimum of five weeks. Competently examined smears and intradermal tests (in this connection the Cole-Levin pus antigen (1935) also deserves mention) should make possible an expeditious positive diagnosis of chancroid in the majority of cases.

The diagnostic problem of chancroid with respect to syphilis, is, however, not met unfortunately by the positive diagnosis of chancroid. Greenwald has most recently insisted that four successive examinations by darkfield have, in his experience largely eliminated the necessity for

the serologic follow-up of blood-tests through the ensuing three to four months. In military practice such incomplete procedure may be enforced by exigency but in civilian practice, the necessity for proving that a chancroid has not been complicated by the onset of syphilitic infection requires invariably and unconditionally the repetition of serologic tests for syphilis on the blood at intervals of a week for one month following the recognition of the chancroidal lesion and once a month thereafter for an ensuing three months. This, the so-called serologic follow-up, is as integral to the air-tight exclusion of syphilis from the diagnosis of chancroid as it is to the exclusion of syphilis as a complication of gonorrhea.

Treatment of Chancroid.—This has been revolutionized by the advent of the sulfonamides. Formerly advanced, rapidly progressive and resistant lesions required every ingenuity of local treatment with soaks and compresses, drainage without rash surgical intervention, and the use of various preparations locally. Out of reach of the sulfonamides, potassium permanganate provides the one probably safest single controlling measure—the hot potassium permanganate soak in a concentration of 1:6,000 to 1:10,000 aqueous solution. With the sulfonamides the answer to the chancroid is sulfathiazole, 4 grams in divided doses for each of seven successive days (10 days, Kornblith).

Other methods of local treatment include soaks with 1:8,000 mercury bichloride solution, dilute copper sulphate solution with fulguration (Robbins and Seabury, Jacob); and, once the lesion is comparatively clean, dusting with iodoform or thymol iodide. An alternative in the case of sulfonamide sensitivity is tartar emetic (Gutmann, Jones), a one per cent solution given intravenously starting with 3 cc. and increasing 1 cc. per injection up to 10 cc. given twice a week (see ulcus molle serpiginosum).

Ulcus Molle Serpiginosum.—This condition, often regarded as chronic chancroid, and often spoken of also as phagedenic chancroid, is not to be confused with the fulminating Vincent infection of the genitalia known as gangrenous balanitis (p. 488). None the less, it is one of the most alarmingly destructive of the entire group of genital lesions and, once its determined march through the skin and subcutaneous tissues is begun, it can be arrested only by almost heroic effort. The essential unit of the ulcus molle serpiginosum picture is the kidney-shaped ulcer with undermined, overhanging, and indurated border, a dark hemorrhagic base and "hilus" of scarred and healing tissue on the convexity of the kidney-shaped lesion. A combination of such units produces the serpiginous border characteristic of the condition and the resemblance at times to late syphilids may be startling and leads to errors in diagnosis. It is not at all an uncommon thing for a single lesion of this type to begin near the base of the penis and to sweep penis and testicles before it in a gradual though sometimes fairly rapid advance, literally "cleaning out" the inguinal and perineal region and extend backward upon the buttocks in a course ranging from six months to three or more years. Patients of this type undoubtedly present a special predisposition of some sort, an increased susceptibility particularly of the subcutaneous fat and connective tissue which makes them an easy prey. In dealing with such a case the physician may confront one of the most difficult of therapeutic problems. The simpler methods already described having failed, even though syphilis is not responsible the patient may be given neoarsphenamine intravenously and potassium antimony tartrate in alternation, and the actual cautery vigorously used in the effort to stop the progress of the advancing lesion. Under local or gas anesthesia the ulcers may be trimmed flat, every trace of the rolled undermined border being done away with and thoroughly cauterized. Pyrogallic acid, beginning with 10 per cent strength and increased to full-strength applications, has been commended where the cautery has failed. In two refractory examples, radium, used to the point of pronounced reaction, gave highly satisfactory results after everything else had failed. Skin grafts may be used to cover denuded areas and hasten epithelialization and sulphhydryl wet dressings and ointments containing oxyquinoline derivatives, among the newer possibilities, might deserve trial.

Lymphogranuloma venereum.—The disease entity designated by this name, official for the American Medical Association, has emerged from the miscellaneous collection of hypertrophic and ulcerative infective processes involving the genitalia and the lower gastrointestinal tract as well as other structures, described through the last quarter-century by a wide variety of terms. Lymphogranuloma venereum is a systemic virus disease with primary localization in the lymphatic system with spread to adjacent structures and now quite well-recognized systemic manifestations. Its importance in the diagnosis of syphilis as well as in venereology in general justifies a rather detailed description of the clinical manifestations.

The virus itself was probably first seen by Gay-Prieto (Findlay) in 1933. It belongs to the lymphogranuloma venereum-psittacosis group of virus diseases which includes trachoma, inclusion conjunctivitis, psittacosis, human atypical pneumonia, acute meningopneumonitis, and mouse pneumonitis (Rake and Jones, 1942). Formerly believed to be a disease of tropical countries, it is now apparent that its distribution is world-wide and demonstration of its prevalence

the persistence of the infection, once established in the individual, the long duration and recurrence of infectiousness, all make it a disease of grave public health significance. Its association with sexual promiscuity while definite, is by no means exclusive. The Negro, as in the case of syphilis, is overwhelmingly more affected than the white race. The anorectal syphiloma and esthiomene, the elephantiasic ulcerative form of lymphogranuloma venereum involving the external genitalia, were for years rated as syphilitic or tuberculous in origin by the most unimpeachable authority. Fournier's description of tertiary lesions of the anus and rectum, "syphilome anorectal" is probably composed almost entirely of the physical characteristics of lymphogranuloma venereum.

Six groups of clinical manifestations afford a convenient classification (according to Grace) on which to base the clinical description of lymphogranuloma venereum. These include:

1. The genital variety of the disease.
   (a) Erosive penile lesions.
   (b) Erosive vulvar and vaginal lesions including esthiomene.
   (c) Elephantiasis of the external genitalia.
   (d) Abacterial urethritis.
2. Inguinal variety of the disease.
   (a) Inguinal adenitis, suppurative and nonsuppurative.
3. Pelvic variety of the disease.
   (a) Inflammatory disease of pelvic tissues.
4. Anorectal variety of the disease.
   (a) Perianal edema, ulceration and hypertrophy.
   (b) Fistula in ano.
   (c) Perianal abscess.
   (d) Anal and rectal stricture.
5. Colonic variety of the disease.
   (a) Ulcerative colitis?
6. Extragenital variety of the disease.
   (a) Manifestations dependent on the site of infection and its associated lymphatic drainage.

Manifestations in other systems are:
   (a) Eye (changes of vessels of the fundus, peripapillary edema, conjunctivitis).
   (b) Bone and joint.
   (c) Nervous system (meningo-encephalitis, meningeal).
   (d) Skin (lymphogranulomatid, photosensitivity).
   (e) Other scattered localizations (upper respiratory, gastro-intestinal, genito-urinary, muscular).

The clinical course of lymphogranuloma venereum of genital origin may be briefly described as follows. The primary sore or lesion usually appears from two to five days after the infective coitus. In the male it is most commonly observed on the coronal sulcus but may appear on the glans, the prepuce or in the urethra. There may also be a balanitis. In the female the inoculatory lesions may occur on any part of the external genitalia, the usual site being the posterior vaginal wall, posterior lip of the cervix, or in the neighborhood of the fourchette. The lesion is a small herpetiform vesicle or ulcer, circular or lenticular, sometimes multiple, with clean-cut edges surrounded by a reddened zone, but with no induration or infiltration. The base of the ulcer is whitish gray and forms a small rounded hollow of pin-head size. The lesion is asymptomatic, heals spontaneously and is often missed both by the patient and the physician. The incubation period is one week or less in 70 per cent of cases, but may be as long as five weeks. The lymphotropism of the virus leads to the development of a bubo in the drainage area of the primary lesion. The incubation period for this manifestation from the time of infection ranges from four days to more than 100, and is most frequently ten to twenty-nine days. The early impression that lymphogranuloma venereum was exclusively a disease of males, as well as the failure to identify the vulvar and anorectal granulomas with lymphogranuloma venereum was a consequence of the lymphatic distribution of the virus. When the primary lesion occurs in the inguinal lymphatic drainage area, whether in male or female, inguinal buboes and esthiomene are the prevailing manifestations. When inoculation occurs in the vagina or upon the cervix, direct extension of the infection through the rectovaginal septum leads to the syndrome of anorectal lymphogranuloma. The bubo localization is prevailingly inguinal and iliac, more frequently the latter, and more frequently unilateral than bilateral. Occasional inguinal, femoral, and inguinofemoral and iliac involvements occur. From the secondary adenopathy first recognized by the patient through a sensation of stiffness and aching followed by swelling, the process may come to an end, or after retrogression, may light up again. The person may then remain a carrier of the virus without active symptoms for

many years The infection usually extends however until all the nodes of the group are involved, with considerable periadenitis, the nodes becoming fixed and adherent to the skin. Inflammatory changes continue, with softening and the formation of abscesses and fistulae, from which characteristically thick, viscid, tenacious opalescent, yellowish-white pus exudes, and from which no organisms can be demonstrated by the usual cultural methods. In a period usually extending from two months to two years, the glandular swelling subsides, drainage is complete, and healing takes place. If the destruction of nodes and surrounding tissue is widespread, secondary elephantiasis of the leg and pudenda may follow or there may be a complicating phlebitis. Extensive and central suppuration of the lumbar nodes, extensive destruction of the psoas muscle, and extension of the infection to articular surfaces, to the kidneys and adrenals of the involved side have all been observed.

The constitutional manifestations include slight fever slight leukocytosis with mononucleosis, increased sedimentation rate and hyperglobulinemia, especially in the later stages. Pulmonary involvement, ocular lesions with regional adenopathy tonsillar ulcers, ulcerative angina,

Fig 2-1 —The primary lesion of lymphogranuloma venereum. (Courtesy of Dr Arthur W Grace, New York)

arthritis at points distant from the site of initial involvement, occasionally simulating rheumatic fever or purulent arthritis, have been recognized. The dermatological manifestations include erythema multiforme erythema nodosum, scarlatiniform eruptions, papular lesions, ulcers and giant keloid formation. Particular interest attaches to the characteristic lymphogranulomatids reported by Saenz (1935) and by Goldberg and Fondé (1936) which are indicative, theoretically at least, of vascular dissemination and allergic characteristics in the disease.

The late lesions of lymphogranuloma venereum include the anorectal syndrome genital elephantiasis with ulceration (esthiomene) and some of the remote system types of involvement just mentioned Of these the anorectal syndrome consisting of inflammatory strictures of the rectum, represents in all probability the most serious form, and occurs predominantly in women Grace (1945) divides rectal involvement into the following clinical types (1) stricture with proctitis (2) stricture without proctitis, and (3) proctitis without stricture Most cases of proctitis without stricture had no history of previous anorectal disease The rest had had perirectal abscess or fistula in no t average interval of 1 7 years About one-third of these cases develop stricture

Unless stricture develops within three years after the onset of anorectal inflammation, chronic proctitis without stricture will result. Men are the predominant victims of this type, and Grace is inclined t believe that the explanation lies in homosexuality In proctitis with stricture, fibrous band, usually single, may extend over several inches of the wall, and occurs most frequently within reach of the examining finger The condition is chronic accompanied by bloody purulent anal discharge, and in the absence of fissure with little pain. An eight millimeter diameter will permit evacuation with the aid of cathartics. The average period before colostomy became necessary (60 per cent of cases) was 7.8 years. Fistula in ano, rectovaginal fistula and perirectal abscess were sequelae in one-sixth of the cases.

Stricture without proctitis develops from outside the bowel wall and is most common in women (61.3 per cent) Stricture without proctitis presents the ppearance of scar tissue diaphragm across the lower bowel with small central aperture. Involvement of the gastro-intestinal tract above the rectum has been subjected to considerable study and controversy for which reference should be had to the papers of Rendich and Poppel (1939) and Paulson (1936, 1941)

Genital Elephantiasis with Ulceration (Esthiomene).—In the earliest phases, small noncharacteristic ulcers of the vulva, anus or rectum may occur which persist, enlarge and disappear only to reappear Elephantiasis consists of moderat to marked swelling of the labia majora and sometimes of the labia minora, urethral and anal folds which form round hemorrhoid-like or lobulated cockscomb-like masses. The involvement of the labia is usually bilateral, one side being more affected than the other and occasionally the clitoris participates in the elephantiasis to such an extent that it may be hypertrophied to ten or fifteen times its normal size and may undergo secondary ulceration. In some cases only abortive forms are seen for a long time such as swelling of the vulva without ulceration, swelling of the anal folds; chronic recurrent abscesses of the vulva, buttocks and so forth. In the male, similar elephantiasis of the penis and scrotum with or without ulceration may occur but is much less common as sequel than in the female. It may occur after surgical extirpation of the inguinal nodes, but also independently

Secondary infections such as erysipelas, severe pyogenic invasion and occasionally carcinoma may occur on the elephantiasic tissue Combinations of the anorectal and genital syndromes are not infrequent. The special student of the rectal pathology and clinical manifestations should read the papers by Cole (1933), by Van der Veer Cornan, and Ullery (1933), by Mathewson (1938), by Bloom (1934 1936) by Bensaude and Lambling (1936) and Stannus (1934)

The Skin Diagnostic Tests.—The importance of lymphogranuloma venereum in venereologic diagnosis and its world-wide prevalence and probable frequency make the performance of diagnostic test for the disease reasonable requirement in every venereologic work-up. The basis for such test was supplied by Frei in 1925 with the discovery that the pus of the inguinal bubo contained antigenic properties which enable it t be utilized in highly specific intradermal test. The technical details of the preparation of the Frei antigen will not be reviewed here, since it seems in process of displacement by the yolksac antigen developed in Rake laboratory and marketed as Lygranum (ST) (McKee, Rake and Shaffer (1940)) Those desiring to review it will find usable description in the report by Beerman, Ingraham and Stokes (Am. J Med. Sci. 197 892, 1939) In 1934 Grace and Suskind described mouse-brain antigen which is effective if controlled with normal mouse-brain emulsion now invariably used to detect nonspecific effect. Rake points out however that the concentration of virus is low leading to doubtful or negative results in patients who undoubtedly have had the specific infection. *The technic of the Lygranum test,* according to the manufacturer instructions and Axelrod' publication (1942), is as follows. 0.1 cc. of the virus antigen and an equal amount of normal chick embryo yolk control is injected t separate sites intradermally into the skin of the forearm, previously prepared with alcohol. Readings are made t forty-eight hours and seventy-two hours, and in many cases were repeated by Axelrod at the end of eek. In interpreting the results of the tests, only the inflammatory indurations were taken into consideration. In the case of erythema, regardless of its extent, whether alone or as zone surrounding papule, it is not considered significant. By positive tests are meant those in which the papule measures at least 7 7 mm. By doubtfully positive reaction is meant one in which the papule is less than 7 7 mm. but more than 5 5 mm. In negative reaction the papule measures less than 5 5 mm.

A complement fixation test employing the yolksac antigen has been used by Shaffer Rake and Grace (1942) and is still in the process of evaluation. One of the objections to it is the tendency to cross positive reactions with other diseases of the lymphogranuloma venereum-psittacosis group but since these are relatively rarely involved in the diagnosis of syphilis, the complement fixation test ith Lygranum CF when evaluated. may be serviceable in detecting the norectal syndrome and so forth.

There are number of indications that cross reactions occur between syphilis and lymphogranuloma venereum in the field of skin and complement fixation tests, and that biologically

false positive serologic test for syphilis may occur in cases of lymphogranuloma venereum accompanied by hyperproteinemia (Cardon, Atlas, Aron, Brunner, Teitelman and Busata (1942).) The precise proportion of biologic false positive serologic reactions for syphilis in lymphogranuloma venereum is yet to be determined.

Treatment.—The use of the sulfonamides and antimony has greatly improved, if not as yet completely solved, the treatment situation in this disease. Grace (1943) employing sulfathiazole in the early stages of lymphogranuloma venereum advises 1.5 grams administered orally three times daily for two weeks, and then one gram three times daily for the next two weeks. A rest period is then allowed, during the succeeding three weeks, after which treatment is resumed, beginning with 1.5 grams three times daily as above. In inguinal cases a second course is not usually considered necessary since this is the most benign group of manifestations of the disease. In the anorectal type of the infection the sulfonamides are also efficient, particularly sulfaguanidine, in the earlier stages of involvement. The later the manifestations, of course, the less responsive to drug therapy. Antimony, effective in apparently nonspecific ways in a number of resistant genital infections and ulcerations, is also used effectively in lymphogranuloma venereum, as reported for tartar emetic and Anthiomaline (lithium antimoniothiomalate (1942) (Shaffer, Fondé and Goldberg (1939)).) Law, from a large British experience, and Shaffer (1943) in further studies, have confirmed the value of antimony. Anthiomaline is administered two or three times a week, preferably the latter—the initial dose being 0.06 gram, and the amount increased in increments of 0.03 gram until the typical rheumatoid pains appear. The dose is then reduced until the pains are just barely perceptible several hours following the injection. The tolerated dosage is usually in the neighborhood of 0.12 to 0.24 gram; the usual course consists of totals of from 2 to 4 grams—12 to 20 injections—at which point the patient is allowed from two to four weeks rest before commencing the second or final course of treatment.

The biologic therapy of lymphogranuloma venereum with Frei antigen has also been favorably reported. Prehn (1937) gives a series of at least 8 injections—one every other day intradermally—close to the site of the lymphadenitis. The intravenous use of the antigen has also been advocated, deGregorio (1937) employing 12 to 14 injections. In all estimations of therapeutic effect, the tendency of the disease to spontaneous recovery must be borne in mind.

Granuloma Venereum.—Granuloma venereum, usually called granuloma inguinale, is a chronic inflammatory process involving the upper layers of the corium, and due to a Donovan body whose recognition intracellularly in smears from tissue is diagnostic. The organism has recently been cultivated in the yolk sac of the chick embryo by Anderson (1943). Some question has been raised as to whether this disease should be regarded as venereal, though Greenblatt and his associates (1939) believe that the point of entry is most commonly about the genitalia, possibly with lymphatic distribution to the skin of the inguinal region. It is distinctly not primarily a disease of the lymphatic system as is lymphogranuloma venereum. The clinical manifestations range often successively through (1) a nodular form, which develops as a plaque 1 to 4 cm. in diameter, reddish in color and soft in consistency. Greenblatt has suggested that this be designated "pseudo bubo" since it is a subcutaneous infiltration and not a lymph node lesion. (2) The ulcerovegetative form, most common clinically, develops by excoriation and maceration with the formation of a rather spongy easily bleeding surface covered with granulating tissue. This spreads peripherally by continuity and new lesions may appear as the result of autoinoculation. In the earlier stages the granulating tissue is clean and pinkish red, the discharge serosanguineous and the surface relatively smooth, whereas in older lesions or in grossly neglected cases the surface becomes more uneven, the discharge seropurulent and foul-smelling, and the granulation tissue changes to a grayish dirty hue. The border is sharply demarcated, indurated and raised above the level of the skin, and occasionally shows a pearling suggestive of epithelioma. The process spreads along the inguinal creases and progresses for weeks and months, finally tending towards healing with trophic depigmented scars in which there is permanent loss of hair. Secondary infections are common in this stage, particularly with spirochetes, aerobic or anaerobic organisms, which tend to deepen the ulceration and necrosis of the soft tissue. So deep may such involvement be that rectovaginal fistulae and perianal phlegmon may complicate the case, ushered in with fever and general malaise. Pregnancy accelerates the pathological process, and one case of malignancy superimposed on granuloma venereum of the cervix has been reported.

The third clinical type is a hypertrophic lesion in which large vegetating masses, sometimes several centimeters high, spring from the lesion. Occasionally an elephantiasic form is observed in which esthiomene-like pictures develop, confusable with lymphogranuloma venereum. In granuloma venereum the swelling is associated with extensive scar formation in and around the involved tissue parts, whereas in lymphogranuloma venereum the skin is thick and edematous but otherwise normal. A fourth type, the cicatricial, is the result of a peculiar reaction on the part of the host to the infectious agent, leading to the formation of keloid-like lesions. The keloid

hypertrophy is not a healing or healed stage of the disease but is progressive and the Donovan body can be obtained by aspiration and seen on histologic examination of the tissue in small nests of inflammatory cells. In older cases of this type, elephantiasic changes in the labia of women are especially likely to occur.

Diagnosis is based on the identification of the Donovan body in smears, especially from the deeper tissue obtained on biopsy. Giemsa, Wright, and silver impregnation stains disclose the organism as a cellular inclusion of "safety pin" shape with densely staining nuclear or polar body at each extremity. Complement fixation tests studied by Goldzieher and Peck in 1926, have been discarded.

Treatment.—All single methods of treatment leave a certain residue of uncured cases, but skillful combination of them may result in cure. Neoarsphenamine in equal parts glycerin and cod liver oil is strongly recommended as a clean-up agent. The most effective drug is antimony whose use as potassium antimony tartrate (tartar emetic) has been standard since 1913 (Aragao and Vianna). It is given intravenously as a 1 per cent aqueous solution, the initial dose 1 to 2 cc., increasing 1 cc. every other day until the maximum of 10 to 15 cc. is reached. Two to three months of this treatment may be necessary before therapeutic response begins. While 20 to 30 injections is the usual course, 50 to 60 may be given without increase in toxic effect. The characteristic reaction consists of nausea, vomiting, diarrhea, and a rather characteristic arthralgia and myalgic pain through the shoulders. Nitritoid reactions are occasionally observed. Fuadin is also highly effective and somewhat less toxic, a 7 per cent aqueous solution being used with the initial dose 1.5 cc., increased every one to two days, up to 5 cc. intramuscularly. The report of Shaffer, Ford and Goldberg (1938) on anthiomaline (lithium antimonythiomalate) indicates that it should also be effective. The chief difficulty in the practical handling of the case is to persuade the patient to persist in treatment for a long time after lesions have healed lest relapse occur. In occasional cases, radiotherapy may assist in clinching a result obtained by other treatments. Robinson and Robinson (1914) proposed surgery for many cases previously considered hopeless. Fulguration of the edges of advancing lesions and electrocautery excision may cure patients previously considered hopeless.

Tuberculosis of the Penis.—This comparatively rare condition is usually the sequel of tuberculous ulceration of the bladder and tuberculous infection higher in the urogenital tract. The lesion is sometimes granulomatous and papillomatous, or fungating, sometimes raggedly ulcerative, involving the meatus and the lower half of the glans, and producing cicatricial contraction. Metastatic extension to lymph nodes we have not observed, though it is described, the lesion being much more suggestive of carcinoma than of any of the genital infections. Primary inoculation tuberculosis in infants following ritual circumcision has been described.

Carcinoma.—Carcinoma about the genitalia is not infrequently confused with the primary lesion of syphilis and *vice versa*. The annular carcinomatous infiltration of the meatus in women is, in fact, so similar to the annular chancre of the meatus that carcinoma is the usual initial diagnosis in such cases. The fungous hypertrophic chancre of the cervix uteri may also be mistaken for carcinoma. Carcinoma of the penis seems to bear a close relationship to phimosis, for it is extremely rare in the circumcised. It is not necessarily a disease of middle or old age. Shivers, 2 of whose 5 patients with this disease were in the third decade of life, points out that the growth exists in two forms, the papillary or cauliflower type and the indurated ulcer variety. The glans and the under-surface of the prepuce are the most frequent sites of involvement. Primary metastasis occurs to the superficial inguinal lymph nodes, followed by involvement of the deep chain and finally the iliac nodes, such involvement occurring much later of course than in the primary lesion of syphilis and being smaller and shottier. Barringer and Bean conclude that involvement of the inguinal nodes occurs relatively late and develops in less than 40 per cent of cases. The treatment is surgical destruction of the growth, local in type if the lesion is early but when the tunic of the glans is penetrated, amputation becomes necessary with extirpation of the inguinal nodes. Irradiation to the lymph gland areas suspected of involvement may be employed but the lymph node enlargement is often inflammatory rather than metastatic.

Laboratory Diagnosis of the Chancre—Darkfield Efficiency.—The efficiency of the diagnostic methods dependent on detection of the organism especially by the darkfield was tested in World War I with conclusive results.

In 1911 in the United States Army the ratio of cases recognized in the primary stage to those allowed to proceed to florid secondaries before diagnosis was made was as 1 to 7. Systematic insistence on modern diagnostic methods including the use of the Wassermann reaction reduced the ratio by 1915 to 1 to 4.5. Yet this is far from ideal and very much short of the possibilities of modern methods. Dudding and Fildes and Dudding of the British Navy in 1917 criticized the efficiency of the Royal Navy Medical Service for a ratio of 1 to 4, and pointed out that in a series of untreated venereal lesions, 65 per cent could be shown to be syphilitic at once by the darkfield alone, and that only 14 per cent of those not thus shown to be syphilitic were ultimately proved to be so by the results of subsequent Wassermann follow-up tests. This percentage sets a ratio better than 1 to 1. Figures representing the efficiency of darkfield diagnosis in the American Expeditionary Forces were reported by Moore, from the Paris district. Of 693 genital lesions, whose diagnosis represented a combination of clinical criteria and at least one darkfield examination, 54.5 per cent were diagnosed chancroid, and 45.5 per cent chancre. Of 135 cases followed for at least eight weeks after the tentative diagnosis of chancroid, and subjected to repeated Wassermann tests, 14.9 per cent subsequently became positive, showing that the original lesion was chancre and not chancroid. These percentages while lower for syphilis than those of Fildes and Dudding will be seen to coincide with them for the margin of error of the modern differential diagnosis of chancre and chancroid by the darkfield. In a table quoted below Moore compares

Fig 252

DIAGNOSIS OF CHANCRE AND CHANCROID IN THE A. E. F (After Moore)

	Total venereal ulcers.	Chancroid.	Per cent. chancroid.	Syphilis.	Per cent. syphilis.
French Army in 1916	18,900	5670	30.0	13,230	70.0
British Army in England up to April, 1917	27,000	6000	22.2	21,000	77.7
Paris clinic	693	379	54.5	314	45.5
American Expeditionary Force	3,480	2628	75.5	852	24.5

his findings with other large groups of statistics collected during the war (Fig. 252). The striking discrepancy between the high proportion of diagnoses of "chancroid" in the A. E. F. (75.5 per cent) and the small proportion of chancroids in the British and French Armies (22 to 30 per cent) Moore explains in part by the fact that the British and French diagnoses were those of experts at concentration hospitals, and hence showed a high proportion of syphilis, while the low proportion of syphilis and the high percentage of "chancroids" in the American forces represent the diagnoses of field medical officers whose acquaintance with modern methods was slight.

While it is only fair to state that part of the difference, as Moore points out, is due to a difference in the prophylactic methods employed by the various armies, the commentary on the comparative ineffectiveness of average medical diagnosis of the chancre as compared with the effectiveness of modern methods is none the less apparent.

Expectancy of Syphilis in Genital Lesions.—It is probably fair to consider that the expectancy of syphilis underlying genital lesions of all types ranges between 60 and 85 per cent with the application of all modern methods to its diagnosis. Wenger and Proske (1930) found in an examination of 1235 patients with genital lesions, that 80 per cent were of syphilitic origin and that of the 14 per cent who did not cooperate in follow-up 12 patients subsequently returned with syphilis. The overwhelming proportion of genital syphilis can be recognized by darkfield examination of the primary sore before the appearance of secondaries, before the appearance of a positive blood Wassermann or precipitation reaction in many instances and before the patient has served

as transmitter of the disease to many of his various genital and extragenital contacts

Influence of Age of Lesion.—The influence of the age of the lesion on the percentage of diagnoses made by darkfield is shown in Fig 253 from a survey made by McFarland and Stokes covering 251 cases of early syphilis, 210 of whom had either a chancre or secondary eruption, or both It will be apparent that the darkfield reaches its highest efficiency in the first two weeks of the primary lesion

Taking treated and untreated chancres alike we were able to identify 82 per cent of primary sores as syphilitic by darkfield up to the fifth week.

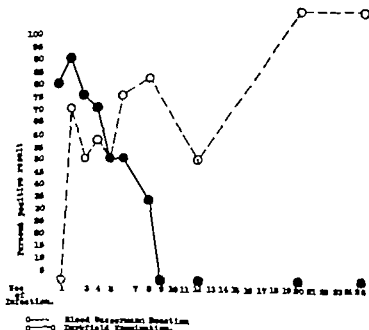

Fig 253.—Chart illustrating the proportion of positive results obtained with the darkfield examination of the chancre and the blood Wassermann reaction in the early weeks of syphilis (Stokes and McFarland)

Thereafter the percentage declines rapidly and leaves us with an average of 66 per cent positive darkfields obtained in the primary stage If the campaign for public education ultimately brings the patient to a competent examiner untreated within two weeks of the appearance of his lesion, a darkfield efficiency of over 90 per cent should not be too much to expect.

Recent Important Facts Concerning Darkfield Examination.—The Cooperative Clinical Group, which has assembled the largest material on early syphilis thus far in existence, has brought forward a number of interesting considerations regarding the darkfield and the early diagnosis of syphilis. In their material of 168 seronegative primary cases the diagnosis was made by darkfield in 91 4 per cent and on clinical appearances, presumably in 8.6 per cent. Positive darkfields were obtained on seropositive primary syphilis in 72.6 per cent, and it was possible, utilizing one lesion or another for darkfield examination to maintain and even improve this proportion of positive darkfield results throughout secondary manifestations in the first year and delayed secondary

manifestations later than the second year This means, of course, that darkfield diagnosis is susceptible of much more extended application as compared with serological tests than has been thought possible in the past The experience of our own clinic confirms this, for it is by no means unusual to obtain positive darkfields even from dry papules of a secondary eruption. Condylomas in the lat primary and secondary stages yielded 90.7 per cent positive darkfield findings while mouth and throat lesions yielded 85.6 per cent positives, and cutaneous lesions 78.3 per cent. It was found that age of the patient has no effect on the proportion of positive darkfield results.

The increasing simplicity and trustworthiness of the skin tests for chancroid and lymphogranuloma venereum will inevitably raise the question as to an appropriate cross-check for the presence of these diseases in the presence of an undoubted syphilitic primary lesion. If the physician can realize that a positive chancroid, Frei or Lygranum test does not in the least modify the fact that the patient may have syphilis if he could be induced to do the dark field *first and the skin-tests afterwards if he can realize that the positive* skin tests do not necessarily mean that the conditions they reveal are actually part of the patient s immediate clinical picture then perhaps after a long, and probably painful process of education routinization of the chancroid and lymphogranuloma venereum skin tests may be encouraged

The ardor of the serologist in advocating the earlier recognition of a seropositive blood in the primary stages of syphilis as a substitute for a darkfield examination must be viewed with only qualified approval. The margin of error of the hypersensitive serologic test probably approaches or even exceeds that of the darkfield, and a crop of false positives in the one case is as likely to match a crop of false negatives in the other as is any other outcome of over enthusiasm It may then be insisted that properly performed darkfield examination within the exceptions previously and repeatedly described has great dependability There should be no hesitation on the part of efficient medical organization in the employment of darkfield examination and the acceptance of its result in the seronegative primary stage of syphilis. On the other hand even competent medical organizations would be well advised to view with conservatism the application of presumptive serologic tests to the diagnosis of primary syphilis. The practicing physician who considers that a patient has not had syphilis unless he has had a positive serologic test on the blood regardless of his darkfield findings, is a not infrequently encountered obstacle to continuous and effective treatment in the seronegative primary stage of the disease

Effect of Local Treatment.—The influence of local treatment in reducing *the efficiency of the darkfield examination is well shown by Driver s series of* 171 chancres, in which a positive result was obtained in 57 per cent. Of these 171 cases, however 90 gave no history of local treatment, and of these 81 per cent gave positive darkfields, while of 81 cases which had been treated locally before darkfield examination only 28.5 per cent gave positive results. Our own observations on this point, while supporting the general principle that "no treatment should be consistently and vigorously preached, tended to show that the fact of previous treatment of the local lesion does not make the darkfield useless. Of 17 chancres in treated patients, 11 or 71 per cent, *yielded positive darkfields Of the 11 patients with positive darkfields, 8 had* had local treatment including cautery and 3 had had arsphenamine and mercury The positive darkfields in the treated cases were obtained by repeated examinations after salt solution soakings.

Aspiration of Lymph Nodes —If the lesion itself after careful and repeated

examination by the technic given in Chapter III fails to yield a positive darkfield, aspiration of the adjacent lymph nodes should be done if they are sufficiently enlarged to be reachable (p 57) This procedure is of the greatest value in suspected chancres about the lips, mouth and throat. That it is effective in genital lesions is indicated by the fact that even with the older "dry" method which has been much improved by the injection of saline or distilled water before aspirating we obtained 50 per cent additional positives in 12 lesions otherwise negative to darkfield.

It cannot, then be too strongly urged upon physicians, or made too prominent a feature of educational campaigns, that the fresh untreated lesion is the one from which the promptest, most accurate diagnosis can be made, and at the same time the one which if it prove to be a chancre offers the patient the best hope of radical cure The methods by which this consummation may be brought about are specially discussed in Chapter III Systematic effort to wean the young man away from the prescribing drug clerk with his calomel powder the ready friend with his home-made acid cautery

or the physician who still "burns em off" is the modern preventive trend in the treatment of syphilis.

Eighty patients in Stokes and McFarland's series had seen physicians before they reached the authors. Seventy per cent had received correct diagnoses, and 30 per cent incorrect diagnoses. This showing, though good, is far from ideal, especially because many of the diagnoses were late rather than early

The Blood Serologic Reaction in the Diagnosis of the Chancre.—The average physician, confronted with a genital or other suspicious lesion and not equipped for a darkfield examination, may if his suspicions are aroused, take blood for a Wassermann test. In doing so he should clearly realize that so far as the earliest possible diagnosis of the lesion is concerned he is employing a method which is at its worst precisely at a time when the darkfield is at its best. He is, moreover deliberately sacrificing his patient a chance for complete "cure." The inverse relation between the two procedures is again shown in Fig 253 In a small series of cases such as this represents, the proportion of positive blood Wassermann reactions at the beginning of the second week is fortuitously high, and seldom averages above 35 to 50 per cent. Hoffmann believes the proportion of authentic positives not to exceed 35 to 50 per cent by the end of the second week. From this point on it increases steadily to 80 per cent or more at the end of the eighth week.

Serological Results in Primary Syphilis.—The advance in the sensitivity of serological tests is well illustrated by the increasing incidence of positive results being obtained in primary syphilis The Handbuch, in figures dating to 1910 gives 60 per cent positives by the eighth week and quotes Fischer as giving 80 per cent positives by the ninth to tenth week. The incidence of positives by the more recent tests such as the Kolmer and Kahn, yield as high as 75 to 80 per cent positives by the end of the second week with the Kolmer test, and 56 to 90 per cent with the Kahn test, certainly represents a tremendous advance in diagnostic effectiveness It is important, however to remember that the appearance of a positive test may be long delayed—in exceptional cases as late as 100 to 120 days after infection. Figures will differ as to whether they refer to date of infection or date of first appearance of the primary lesion and it is possible that some of the apparent advantage of present-day tests results from a difference in interpretation on this point.

The Serological Follow-up.—If the initial and repeated darkfield examinations are negative and the blood tests are reported negative, the patient should under no circumstances be considered as proved nonsyphilitic He must then at once be placed on the so-called "serological follow up to detect the development of the infection regardless of the characteristics of the lesion or the appearance or nonappearance of secondaries It is inexcusable at this stage in our opinion casually to begin the systemic treatment of a case because it "looks like syphilis, or to fail to follow it up by serological tests because it "doesn t look like syphilis If the examiner has been forced to give up hope of a positive darkfield and cannot utilize the local Wassermann he may begin local treatment of the lesion, but he must not begin systemic treatment short of diagnosis without full realization on his part and the patient s that it must be followed through in full as if the diagnosis had been made

It can at least be said that if treatment is begun without a diagnosis it should be followed through on a maximal basis as if the diagnosis had been syphilis The monorecidives and neurorecurrences which one observes as a result of any other practice are most unfortunate affairs

Frequency of Blood Serological Tests in Follow-up.—Since the purpose of the serological follow up is to obtain a positive result as early as possible, the tests should be taken at shorter intervals early in the course of the lesion and at longer intervals later A daily blood test on the darkfield-negative chancre is ideal but seldom practicable. A test once or twice a week until the lesion is six weeks old is usually possible in dispensary and hospital practice or with the cooperation of state or municipal laboratories If this requirement cannot be met, the age and general appearance of the lesion must be taken into account. In an older lesion the second test may be taken at a shorter and in a fresh lesion after a longer interval from the first visit. Blood serological tests on the fourth eighth, and twelfth week after the appearance of a lesion with negative darkfields can be regarded as an absolutely minimum requirement. We believe furthermore that one more test should be taken four month after the appearance of the lesion inasmuch as cases are occasionally known to have an exceedingly long secondary incubation period

Physical Examination Essential.—It should go without saying that the repeated serological tests should be accompanied by a periodic examination of the patient completely stripped in a good light The mucous membranes, anal region palms and soles should be given special scrutiny Inquiry should be made at the same time regarding the preroseolar constitutional symptoms,

particularly headaches, loss of weight, anorexia, malaise, and arthralgias. These symptoms often appear some time before eruptive manifestations, and

TONSILLAR CHANCRE (?). TONSILLECTOMY. CERVICAL ADENITIS. POSSIBLE ERRONEOUS INTERPRETATIONS DUE TO INCOMPLETE EXAMINATION

Girl aged nineteen years.

11/29/19 **Examined.**

Nose and Throat Specialist's Examination

Chief Complaint Tonsillitis, swollen glands.

10/15/19 **Tonsillitis, severe**

11/1/19 **Tonsillectomy (?)** Glands did not subside. No pain or tenderness.

11/29/19 **Otolaryngologist's Examination** (verbatim) "Small ulcer with pus, upper part of hard palate. Tonsils 3 (large) right. Large left stub with much induration. Soft plugs right marked granular pharyngitis mucopurulent material in nasopharynx. Nose and ears nothing of note. Gland, size of a walnut, right cervical region.

"Summary question of lymphosarcoma or Hodgkin's. Wassermann test to rule out syphilis. Does not resemble tuberculous glands. History of repeated attacks of tonsillitis each winter. General health good.

Transferred to Syphilologist when Serum Wassermann Reaction was Found to be Strongly Positive.

Dermatosyphilologist's Examination

Chief Complaint Positive Wassermann reaction and sore throat with glandular involvement.

11/30/19 Differential count negative.

12/2/19 **Syphilologic Examination** (verbatim) "Cervical adenitis described. Hair thinned. Small patches of depigmentation on neck. Across upper extremities, shoulders, and upper thorax faint maculopapular eruption, only visible by cross illumination. Apparently involuting roseola.

"*Genitalia.* Right labium majus, several small eroded papules and a large irregular ill-defined indurated plaque size of dime. Labia minora eroded.

Mucous membranes. Erosion of hard palate, darkfield positive for *Spirochæta pallida.* Mucous patch left anterior pillar.

General adenopathy.

Vaginal introitus intact.

"Genital lesions present one and one-half weeks.

DISCUSSION

1. The two examinations are paralleled and quoted verbatim to show the difference in point of view.

2. Persistent painless cervical adenitis associated with a throat or lip lesion should arouse a suspicion of syphilis and lead to an investigation by darkfield, gland aspiration, serological tests, and complete physical examination.

3. Specialists whose work is sharply limited to a particular region or group of structures are especially prone to overlook syphilis by missing its collateral manifestations. Every specialist should make a rapid general examination by a good light if he wishes to recognize the syphilis which passes through his hands.

4. This patient sustained a partial tonsillectomy for a probable tonsillar chancre, and her medical adviser proposed an excision of the glands, constituting the satellite bubo of her tonsillar chancre on a presumptive diagnosis of tuberculosis, because he overlooked the possibility of syphilis. The otolaryngologist did not place the possibility of syphilis first instead of last, because he did not see the skin and genitalia. He suspected lymphosarcoma or Hodgkin's disease.

5. The intact vaginal introitus does not prove a tonsillar chancre as against a genital chancre. Mere contact without consummation of intercourse may result in infection. The circumstances of the case and the cervical adenitis make a tonsillar primary lesion the stronger probability.

6. Many tonsillar chancres are operated on each year through failure: (1) To suspect cervical adenitis of being a satellite bubo; (2) to order a darkfield on an erosion; (3) to consider syphilis before diagnosing Vincent's angina; (4) to make a serological test on every patient with a bad throat, and (5) to inspect the skin by a good light in every patient with a bad throat.

may warn the patient to report for examination before the time set for the next blood test appointment. The patient should therefore be instructed to be on the lookout for them.

Follow-up by repeated serological tests deserves the widest application in the management of all types of venereal disease and of every lesion, genital or extragenital, which has aroused the slightest suspicion. Diagnostic knowledge has progressed far enough now to make it absolutely unjustifiable for any physician to give his patient a final diagnosis of chancroid until four months have elapsed from the time of appearance of the lesion. Suspended judgment during this time would increase the amount of early syphilis recognized from 15 to 50 per cent.

Serological Follow up in Gonorrhea and Extragenital Lesions.—This should also be applied to all patients with gonorrhea even in the absence of a genital sore. Friedman's method for the identification of *Sp. pallida* in gonorrheal pus and the identification of the intraurethral chancre masked by gonorrhea has been discussed (page 58). Systematic adoption of this procedure would identify at an early stage 10 per cent of syphilitic infections in which no history of onset other than that of gonorrhea can be obtained. Systematic application of serologic follow-up to lesions in the mouth and throat would, without question, quite transform our conceptions of the extragenital onset of syphilis and would nip many a tragedy in the bud.

CHAPTER XII

THE DIAGNOSIS OF EARLY SYPHILIS—THE SECONDARY STAGE

There is no sharp demarcation between primary and secondary syphilis, immunologically or even clinically speaking The statement that the average interval between the appearance of the chancre and the development of secondary manifestations is eight weeks must be interpreted with numerous reservations. On the one hand definite constitutional symptoms and objective signs of generalized syphilis of the nervous system may be recognizable within a week of the appearance of the chancre On the other hand, the chancre may have been healed for weeks before any cutaneous or constitutional symptoms appear As a third possibility probably not rare, both cutaneous and systemic evidence of the generalization of the infection may be entirely lacking. As high as 60 per cent of patients found to have syphilis in later life can give no history of secondary lesions of any description. The mere fact that a patient has lost no hair had no sore throat or cutaneous eruption and no constitutional symptoms following a genital lesion is not the slightest proof that the lesion was not the onset of a syphilitic infection.

The proportions of various manifestations of secondary syphilis observed *on admission* in 2209 patients in the Cooperative Clinical Group material was skin 81 1 per cent throat and mouth 36.3 per cent genital lesions 10.9 per cent central nervous system, symptomatic 1 7 per cent asymptomatic 8.2 per cent alopecia 7 1 per cent eye lesions 4 per cent visceral lesions 0.2 per cent. Only a part of the patients were examined (CSF) for asymptomatic neurosyphilis on admission, which explains the small proportion.

Diagnosis of Secondary Syphilis Now a Serological Problem.—In pre-Wassermann days the identification of the secondary eruption was a differential diagnostic problem for the dermatologist, and often one of the first order of difficulty With the introduction of the serological tests the diagnosis of secondary syphilis as the sequel of a primary lesion has become practically entirely a laboratory issue. It can be said with as much positiveness as is allowable in any phase of medical diagnosis that a cutaneous eruption, general in character developing in conjunction with the evolution of a suggestive genital lesion, is syphilis, if the Wassermann, at first negative becomes positive during the development of the eruption, and *remains so* without treatment. Nonspecific positive Wassermann results in pityriasis rosea, in tuberculids, and in atypical cases of the acute exanthemata, especially measles and scarlet fever are eliminated by the last proviso.

The high efficiency of the blood serologic tests in the identification of florid secondary syphilis does not, however, do away with the need for comprehension on the part of the physician of the essential characteristics of secondary syphilis. The presence of the secondary eruption may be the only sign to arouse the suspicion of the physician to the point of taking blood test. When the primary lesion is concealed or overlooked, as so frequently occurs in women, and not infrequently in men, or nonsyphilitic eruption is associated as coincidence with positive Wassermann or precipitation test due to intercurrent syphilis, or when treatment has weakened the test or made it temporarily negative, morphological differentiation resumes its full importance. Even when the association with positive blood serological reaction suggests the syphilitic nature

of an eruption, an alert clinician should not rest satisfied without a clear-cut understanding of the why and wherefore of the morphological diagnosis.

There is a noticeable tendency in the literature as well as in teaching to give the serological tests less than their just measure of confidence in florid secondary syphilis. Writers on the test take pains to guard themselves in allowing for the small percentage of untreated acute secondary cases with negative blood Wassermann reactions by needlessly cautious statements, and by endorsing the diagnosis of an untreated secondary eruption over the head of a negative Wassermann reaction, if its appearance seems to support the opinion. Such a point of view deprives the test of a well-deserved confidence. We have in our records and can recall many instances in which lichen planus and pityriasis rosea have been diagnosed syphilis because of a certain distrust of the repeatedly negative Wassermann reaction in the eruption stage. The dilemma in deciding the status of an early eruption becomes acute when as a result of ineffective treatment, lesions recur but the blood test remains negative (Fig. 256).

The Darkfield in Diagnosis of Secondary Syphilis.—Much time may be saved in waiting for serologic tests and clearing up diagnostic puzzles by developing a technic of darkfield examination of secondary cutaneous syphilids.

Fig. 256.

POSITIVE WASSERMANN TESTS IN FRANK SECONDARY SYPHILIS

	Per cent.
All cases as they come, treated and untreated	92 0
Some treatment, but not enough to cause complete involution of secondary lesions	95 7
Untreated cases	98 5
Cooperative Clinical Group, secondary stage	99 0

Superficial scraping of macular and papular syphilids to the point of exposing the lymphatics or with very slight exudation of blood makes it possible to identify *Sp. pallida* occasionally in the most unexpected fashion. Since the lesions used for this purpose are ordinarily on the glabrous skin, the confusion elements encountered in the darkfield examination of vegetative and eroded syphilids in the anogenital region can thus be avoided. The value of the dark field in the identification of secondary syphilis with a negative blood serologic reaction is also considerable. With proper precautions to prevent the confusion of saprophytic spirochetes with *Spirochaeta pallida* a diagnosis of syphilis can be made by the ensemble of the case plus the finding of the organisms, even without a chancre or history of exposure. In the series studied by McFarland and Stokes 7 such cases appeared in a total of 231. In 5 of them the presence of *Spirochaeta pallida* in lesions examined by darkfield was decisive of the diagnosis. Where genital secondary lesions of the condylomatous type are present, the experience of the Cooperative Clinical Group indicates that 90.7 per cent will yield positive darkfields with 85.0 per cent positives in mouth and throat lesions and 70.3 per cent positives in all cutaneous lesions including condylomas.

Diagnosis by Ensemble.—Diagnosis by the ensemble of the case is sometimes the last resort, and should in general be made after consultation if possible. Atypical eruptions of lichen planus and pityriasis rosea will furnish

the chief possibilities of error The mere combination of a genital lesion and an eruption, or an eruption with mouth lesions cannot be accepted as establishing a diagnosis of syphilis.

Secondaries, But No Primary.—One of the interesting and suggestive details of the study of early syphilis was the proportion of patients who although presenting obvious secondary lesions, had no evidence of a primary lesion at the time of examination and could give no history of one. Twenty-four per cent of the series of 231 cases including men and women, with all types of lesions, gave no evidence in history or examination of ever having had a chancre. The general bearings of such observations have been discussed in the preceding chapter and in Chapter I (asymptomatic carriers)

The Dermatology of Early Syphilis.—Figure 258 taken from McFarland and Stokes's series of 231 early cases, serves as an excellent introduction to the dermatology of early syphilis because it indicates the type of lesion which one must expect to encounter in dealing with the generalization of syphilis, and possibly why it is so often said by men working under unfavorable conditions that they never see secondary syphilis. The tendency to illustrate textbooks with wall paper syphilids—large papular pustular varioliform, annular rupial—is regrettable because it leads the student to expect cutaneous syphilis to be glaring and obvious, when in reality it is fugitive, inconspicuous,

Fig 257

HISTORY OF CHANCRE

	Per cent

Men	82	18	83	17
Women	56	44	64	36

and easily misinterpreted. The inconspicuous syphilids, in our experience many of which cannot be and were not seen by competent men under the average office lighting conditions, total 86 per cent of the entire group of secondary syphilids observed. The visible, obvious syphilids, which it is a pleasure to photograph and to present before a class, did not exceed 14 per cent of our group In fact, our group included examples even of the almost "extinct" macular follicular syphilid, which we were able to recognize under favorable lighting conditions.

Aids to Detection of Secondary Eruptions.—Of material assistance in identifying these difficultly visible early syphilids is the ability to observe the patient for the twenty-four hours following his first arsphenamine injection. This utilizes the therapeutic shock and confirms or negates the impression made on first examination. The physician who examines patients in a small room, in which he cannot secure distance and varying angles of illumination, who works by poor daylight or artificial light in the average dispensary night clinic, or first-floor office; or who gives his patient a first dose of arsphenamine and does not see him again for a week, cannot, with the best intentions, recognize much of the early cutaneous syphilis which passes through his hands. The male patient overlooks his eruption and cannot, therefore be relied on to bring it to the attention of an examiner In women, who may present no sign of a primary lesion to arouse suspicion, favorable lighting conditions for the recognition of the inconspicuous syphilids are particularly important. Wherever inspection is being made the basis for a recognition of venereal disease, as in industrial and military medicine, this vital consideration of proper illumination must be borne in mind if the best results are to be secured.

Vasomotor Factor.—The attempt to identify roseolas in cold rooms, especially if suspicion is already aroused to sharp pitch by the presence of genital lesion, may lead to serious mistakes through the misinterpretation of an accentuated marbling of the skin, the normal cutis marmorata, for a macular syphilid.

This is especially apt to occur in patients with "vasomotor skins," which express their emotional stress. Even a patchy follicular eruption can be momentarily suggested to the novice by causing the chilled or nervous patient to "goose flesh" locally by touching him here and there upon the skin of the flank and back. While these considerations rarely trouble the expert, the student may at times find himself on the verge of self-deception in his enthusiasm.

Racial and Sex Differences in Cutaneous and Mucosal Secondary Syphilis.—Early skin manifestations appear fewer in colored than white patients, being probably masked by pigment and fewer in colored women than white women or males of either race. Mucosal secondary lesions other than condylomas are more common (10 per cent) in white than colored patients. Condylomas (p. 535) are more frequent in women than men and the colored woman holds an unenviable record in this regard, these infectious lesions being 3.5

times as common as in the white male, 3 times as common as in the colored male and more than twice as frequent as in the white female (Cooperative Clinical Group).

MORPHOLOGY OF CUTANEOUS SECONDARY SYPHILIDS

Secondary syphilids combine five lesions with five attributes or qualities as follows:

1. *Lesions.* Macule, papule, pustule, "follicule," scar.
2. *Attributes.* Distribution, configuration, association, induration, indolence.

Color.—While the indolence of a lesion is to some extent indicated by the height of the inflammatory coloring and the admixture of chronicity due to pigmentation, color is relatively seldom a necessary element in the differentiation of syphilids. To be sure, the violaceous color of the eruption of lichen planus has weight at times, and the fawn-colored center and pink border of the annular lesion of pityriasis rosea is helpful in identification of this important lesion. But so much diagnostic error has arisen from the misuse of the "raw-ham" and "copper-colored spot" conceptions that, for a time at least, the mind of the student should be disabused of the notion that a colored plate or a colorful eye is in any way necessary or even trustworthy in the diagnosis of early syphilis.

No Vesicles in Adults.—An almost unexceptionable rule of thumb may be found for all practical purposes in the statement that if vesicles are an essential part of an eruption in an adult, *the lesion is not syphilis*

While vesicular syphilids in adults have been described, they are like diffuse syphilitic dermatitis and syphilitic erythema nodosum, rarities of the first order and not as yet entirely above dispute. For the average practitioner they certainly have no meaning at all in the everyday work of diagnosing early syphilis. It should be noted that the bullous syphilid of infancy is excepted.

Rules of Thumb on Distribution.—The early secondary syphilids, as may be expected from the distribution of the *Spirochaeta pallida* at the time they appear tend to be universally distributed over the surface of the body Certain syphilids show a tendency to localization expressed in Fig 259

Variations are numerous, and subforms of the various types, such as the annular papular and psoriasiform papular have distinctive little peculiarities of localization at times. For example, the following should be borne in mind

The papular phase of the macular eruption, if the two are combined, tends to appear upon the mucous membranes as mucous erosions, and on the palms and soles as papules.

The maculopapular eruption tends to be associated with condylomata at the anus and in the flexures.

Fig. 259.

LOCALIZING TENDENCIES OF EARLY SYPHILIDS

Type.	*Localization.*
Macular:	Flanks and abdomen, shoulders, upper arms, back, and chin
Papular	Same as macular, but with an increased predilection for face, palms, and soles.
Pustular	Face and scalp. The rupial and other severe types may be universal. This is the varioliform distribution.
Follicular	Back and extensor surfaces. Scalp (alopecia)

Annular secondary syphilids occasionally appear upon the face in white patients. They are much more common and of more general distribution in the colored patient.

The follicular eruption cannot appear upon the palms and soles because in these sites there are no hair follicles.

An involuting papular eruption tends to persist longest in areas of vascular stasis or congestion, provided they were included in its original distribution as in the case of the papular and pustular syphilid about the rosacea area of the face and on the dependent parts of the extremities (palms and soles)

A macular eruption is usually best seen just posterior to and below the axilla or over the shoulder

Early syphilids, in seborrheic persons, tend to be accentuated in the areas of predilection for seborrhea—the scalp presternal and interscapular regions.

Configuration.—Grouping of lesions and annular or ring-shaped configurations always bring syphilis into the differential diagnosis. While this is more especially true of late lesions, it is of very great importance in certain early syphilids. The clumping of lesions is best illustrated in the corymbose and the grouped follicular lesions. A corymbose lesion consists of a central large lesion, usually papular surrounded by a group of lesser satellites (see

Fig 260—A coarse macular syphilid. (Collection of Dr H W Stel agon.)

Fig. 261.—A small macular secondary syphilid. The photograph was taken by arc (ultraviolet) light which increases the distinctness of the eruption. It is seen with difficulty by daylight. The eruption had been overlooked, and the extragenital chancre diagnosed furuncle.

ing is, however a common characteristic of two other types of follicular lesions, the dermatophytid, and the tuberculid known as lichen scrofulosorum.

A special interest attaches to the follicular syphilid because of its demonstrated association with neurosyphilitic involvement. On the skin the follicular syphilid is produced by infiltration of the hair follicle. On the scalp this infiltration of the hair follicle is accompanied by loss of the hair producing the patchy moth-eaten alopecia of secondary syphilis (Fig. 345) Alopecia is more frequent in white females than white males, and twice as frequent in white as in colored females (Cooperative Clinical Group) Wile has shown that there are two types of alopecia, one of them due to the grouped infiltrative syphilid of the hair follicle, the other presumably to a lesion of the cervical sympathetic ganglia without direct involvement of the hair follicle itself

Fig. [illegible].—Remains of maculopapular syphilid the atrophic macular syphiloderm. The patient had syphilitic encephalitic process.

This highly interesting and important discovery may have important bearing on future work upon the mechanism of development of cutaneous syphilids.

The pustular syphilid is comparatively uncommon though more frequent in the Negro. A few pustules may form part of the picture of a papular syphilid about the nose and forehead. The typical pustule is indolent, often simply softened in the center and crusted over rather than actively inflammatory and pus containing, so that, unless a careful distinction is drawn between crust and scale, a pustule may be taken for a greasy psoriasiform papule. The giant pustular syphilid, for it is really such, is called rupia (Fig. 99) It is more common as a recurrence than as part of the original secondary eruption. The lesion is a cold, indolent ulcer whose crust through successive accretions from below as the lesion enlarges, heaps up into a lamellated pyramidal hardened mass of a conical or oystershell configuration

Residua and Scars.—The macular syphilid rarely leaves even the faintest traces. The scars of secondary syphilids of the papular type, when they develop, are the results of destruction of elastica by the lymphocytic infiltration in the corium and take the form of macular atrophy (Fig 262) Even very slight degrees of papular infiltration scarcely detectable as such clinically may give rise to this atrophy which however is one of the more unusual lesions. The majority of papular eruptions, even of an extreme grade, involute without leaving a trace, though increased pigment may persist for a time. The pigmentary syphilid, so-called (Figs. 446 447) is, properly speaking, the residuum of a papular syphilid, and consists of depigmented macules on a

Fig 263 —An unusual type of pityriasis rosea, simulating macular syphilid. Differential diagnosis in Fig. 270.

hyperpigmented base It will be considered among the cutaneous landmarks of latent and late syphilis.

Infectiousness of Cutaneous Syphilids—The dry uneroded early cutaneous syphilid is noninfectious so far as contact is concerned The pustular and rupial types are self-sterilizing so to speak. Macular and papular lesions which occur in flexures or crypts such as the axillary and inguinal folds, under the breasts or in the umbilicus, may erode and assume the characteristics and infectiousness of mucous lesions. In men a careful search of the scrotum and of the balanopreputial folds should always be made. (See Figs. 417 418 in the discussion of relapse Chapter XIII Identical lesions occur in florid secondary syphilis.)

The Lesions of the Mucosae and Mucocutaneous Junctions in Early Syphilis.—This important type, which is practically synonymous with the infectious lesions of secondary syphilis, included 58 per cent of 183 patients with secondary syphilids in McFarland and Stokes' series and 56.2 per cent in the Cooperative Clinical Group's 2260 patients on admission. Seventy-five per cent of the women and 64 per cent of the men in our series had lesions of this type, a proportion of women which is somewhat lower than the usual, possibly because routine speculum examinations were not made. Women present a much higher proportion of infectious lesions than men and colored women highest of all.

First among lesions of the mucous membranes should be mentioned syphilitic sore throat, a diffuse inflammatory involvement of the pharynx and tonsils, with extensions of varying degrees of severity into the naso-

Fig. 294.—The coarse macular exanthem of leprosy. The hands of this patient are shown in Fig. 485; the differential diagnosis in Fig. 271.

pharynx and larynx. The grade of inflammatory change may vary from the most trivial reddening with a sense of dryness, to extensive diphtheroid involvement with the formation of pseudomembrane and even of extensive necroses and sloughing. Tonsillar changes in syphilis are, however, more apt to be of the erosive type, the tonsil being swollen, red and boggy at the base, with a thin grayish or pearly exudate partially or completely covering the surface. Edema is usually marked and there is a striking accentuation of the lymphatic follicles, as in a follicular or granular pharyngitis. Extension into the larynx results in redness and edema of the cords, with corresponding impairment of function. Hoarseness can often be detected when no gross involvement of the pharynx is visible, and may serve as a valuable clue to an otherwise obscure infection. Complete aphonia lasting for weeks may occur with an abrupt onset and recovery at times suggestive of an hysterical origin.

An inspection of the vocal cords may at times be the only means of identifying the real nature of the trouble.

Mucous Patch.—The typical lesion of the mucous membranes in early eruptive syphilis is the so-called "mucous erosion" or mucous patch (Figs. 364 412, 428) This is essentially the homologue of a macular or maculopapular lesion on the skin whose surface has been eroded by the moisture and friction to which it has been subjected. Local irritation moisture, and trauma, which act as predisposing factors, tend to make these lesions appear about the surfaces of tongue, buccal mucosa, and lips. The typical mucous patch is slightly raised above the surrounding surface, very faintly inflammatory and presents a smooth round or oval central erosion covered by a flesh-colored to pearly or faintly grayish delicate membrane When this is removed the base is seen to be clean, flat, and of a flesh or pinkish color rarely with a tinge of yellow Mucous lesions are seldom less than 5 mm. in diameter and are frequently from 7 to 10 mm. in their greatest diameter They are comparatively painless. If the papule occurs on a constantly moving surface like the side of the tongue, the erosion or mucous patch may be irregular angular or stellate may be deeper and approach the ulcerative type. On the other hand if the papule occurs on the dorsum of a tough-surfaced structure such as the tongue, there may be no erosion, and the lesion remains a papule of a dark pink or reddish color flat, and smooth, but not eroded, and free from papillary markings. A group of them on the dorsum of the tongue may become confluent, forming a large smooth flat plaque.

Where secondary infection is a factor or the syphilitic infection is of unusual severity secondary mucous lesions may become ulcerative and cause scarring and destruction comparable to the effects of the rupial and pustular syphilids upon the skin Ulceration in mucous syphilids is an expression of lateness (recurrence) malignancy or of a precocious tendency to gummatous change The ulcerative mucous syphilid should be especially looked for in the pharynx and on the tonsil.

Genital Mucous Lesions.—Mucous syphilids about the genitalia are more common in women than in men, because the conditions about the female genitalia—moisture, friction, and a certain degree of irritation from detritus and saprophytic infection—are especially favorable to their development. They may occur upon the cervix as well as the more external moist structures. They may include macules, erosions, papules, ulcerations, condylomas—appearing either early in the generalization of the infection or later in infectious relapse, and all these types of lesions may appear successively in the same person. A yellow-based ulcer with fine pink striations is also recognized. It is important to realize that quite as typical a mucous patch may develop under the foreskin of the penis as on the labium minus or at the introitus, and that it may be fully as effective in transmitting the disease. Moreover a penile papule dry at the outset (Fig. 417) may be converted into a mucous erosion by the mere process of coitus, and serve as a source of infection for a healthy partner The special tendency to develop mucous lesions observed in prostitutes has many times been pointed out, and is the natural consequence of the combination of irritation and uncleanliness they so frequently present. That this single fact has the gravest meaning in the transmission of the disease is self-evident.

Evanescent Character—The evanescent character of mucous lesions deserves special emphasis. They may be here today and gone tomorrow *It is*

not at all impossible for a throat which on one examination presents no more than a mild angina, to be the site of a tonsillar or buccal mucous patch at an examination twenty four hours later A superficial erosion may become almost unrecognizable even without treatment in the course of two or three days. Two or three weeks is, however a much commoner life for this type of lesion. The evanescence combined with the painlessness of the lesion explains that often emphasized but too little appreciated statement that the patient who has syphilis may never present a symptom to lead him to consult a physician or to warn him that he is dangerous to others.

Condyloma.—Condylomas (Figs. 300–303) are essentially vegetative hypertrophies of the cutis and epidermis, which are not by any means distinctively venereal or syphilitic in origin. Superficial erosions about the anal and genital regions in particular may become hypertrophic no matter what may have been the original cause of the erosion. The condyloma as such is not, therefore, distinctly venereal. Every transition stage from mucous patch to enormous cauliflower vegetations may be found in syphilis. Even the primary lesion of syphilis itself may conceivably present the appearance of a papule which following erosion has undergone vegetative hypertrophy and may then be diagnosed a venereal wart.

The flat wart or condyloma latum is usually syphilitic, as distinguished from the pointed or filiform papilloma or nonspecific condyloma acuminatum. The typical condyloma latum begins as a raised, slightly mammillated or smooth papule, with a moist eroded surface. As the hypertrophy progresses, the lesion stands higher above the skin and usually mushrooms out somewhat over a thick short stalk or forms a button-like plaque with a smooth surface. It rarely becomes pedunculated. Linear condylomas may develop in fissures. Neighboring lesions may become confluent, forming soft spongy masses with a cauliflower structure obscured by the erosion of the surface and by a thin grayish pellicle of exudate similar to that covering the mucous patch. Necrotic débris, rich in saprophytic organisms, and especially *Spirochaeta refringens* easily collects and obscures the bacteriological picture. The pointed variety (condyloma acuminatum) is much more commonly associated with the discharge of chronic infections of the genito-urinary tract, especially of gonococcal origin. The surface of this type of lesion is more papillomatous and even fimbriated, and pedunculation is not unusual. Both the broad and the pointed condyloma may be confused with the ordinary wart produced by a filtrable virus, which is so common upon the hands and fingers. When this lesion develops upon the genitalia (Fig 304) while it remains fairly dry and often has a hard surface, it assumes a mammillated or cauliflower aspect that may suggest a venereal condyloma. It has, in fact, been recently contended that the two are identical.

Condylomas rarely appear about the oral mucous membranes and mucocutaneous junctions or on the male genitalia. On the other hand, they are common about the female genitalia, appearing in the folds about the labia and on the inner aspects of the thighs and groins. Transition stages from the dry papular lesion of the skin to the moist cauliflower vegetation can be seen in such sites. Under conditions of congestion, irritation, and filth they may reach enormous size, entirely obscuring the surrounding structures. The entire vault and floor of the vagina may be transformed into a mass of condylomatous vegetations. In both men and women the anal region is a favorite for condylomatous hypertrophy of papular lesions.

Darkfield Diagnosis of Vegetative and Mucous Lesions.—The diagnosis of the mucous and vegetative lesions of early systemic syphilis, like the diagnosis of the primary lesion and the secondary eruption has been greatly simplified by modern laboratory methods. The darkfield in particular is a useful aid. Of twenty four darkfield examinations taken on mucous patches and condylomas in McFarland and Stokes series, 23 yielded positive results. Here again treatment in 8 cases did not prevent our obtaining a positive darkfield, and the darkfield was negative in only 2 treated cases. Positive darkfield examinations were obtained on 90 " per cent of condylomas and on 85 6 per cent of mouth and throat lesions in the Cooperative Group series. While the bacteriological picture in lesions deep in the mouth or throat must be interpreted by an expert and may be deceptive, lesions about the lip are usually cleaner and if spirochetes are abundant after wiping the lesion, as they usually are, the diagnosis is practically established

In lesions both of mouth and anogenital region, the morphologically similar *Sp. microdentium* can be cause of confusion. In recently observed case, *Sp. pallida* like organisms were found on the slightly verrucoid surface of superficially eroded pigmented nevus. Simultaneously the patient developed positive blood serologic test which subsequent study indicated was post-vaccinal. The gravity of the risk of not treating this particular patient, nd the confusion elements in the findings led to the use of ten-week intensive arsenotherapy during which the serologic test became negative, but the pallida-like organisms required two weeks (six mapharsen injections) for disappearance The patient is now clinically and serologically normal.

The condyloma must be thoroughly cleaned and even vigorously abraded or the top sliced off before examination if the result is to be trusted, but the serum usually so swarms with typical *Spirochaeta pallida* that there is little room for doubt as to the diagnosis. The finding of an occasional spirochete in mouth or genital lesions cannot be trusted when unsupported by other findings.

THE DIFFERENTIAL DIAGNOSIS OF EARLY CUTANEOUS SYPHILIS

The differential tables here given aim t strike salient points and to give rounded picture of differences, which ma occasionally slight special point on which the hole story in given

A B

Fig 243 —Macular seborrheic dermatitis in its t typical localizations bet een the scapulae and over the sternum. Not the tendency to confluence The lesion have faint, greasy yellowish scale

case will depend. T make the illustrations nd the differentiations cover everything that may ever in any aspect simulat syphilis, or which syphilis *itself* may ever *simulate*, ould require text-book of dermatology and an atlas of large proportions. Only experience makes the complete differentiation and furnishes the background for the indispensable though often abused diagnostic instinct which marks the adept.

Macular Syphilids

Macular Lues II and Macular Seborrheic Dermatitis.—In seborrheic persons these two conditions may coexist, and the diagnosis of secondary syphilis be entirely overlooked if merely the skin be relied upon for clue (Fig 206) For this reason it is essential t carry through the com-

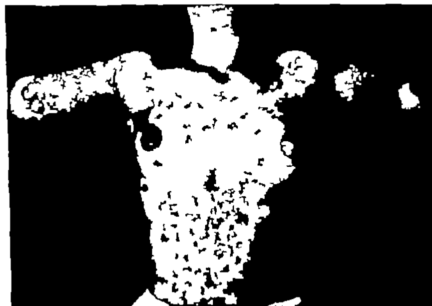

Fig. 206.—The seborrheic mask of secondary syphilis. A macular secondary syphilid assuming the characteristics of seborrheic dermatitis hen superposed upon seborrheic base. (Collection of Dr Grover Wende.)

Fig. 207

MACULAR SEBORRHEIC DERMATITIS	MACULAR LUES II
Predilection for nose, cheeks, postauricular presternal, and prescapular regions, axillae and groins.	None on face (except mottled chin"), least often marked on front of chest.
Rare in flanks and on shoulders.	Most common in flanks and over shoulders.
Fine yellowish greasy scale.	N scale Lesion pink, not yellowish (Maculopapular syphilids may scale.)
Tendency to become confluent in the larger folds.	Remains discrete.
May find minute vesicles, or lesions may become eczematous.	Never vesicular no oozing or crusting.

plete examinat ion on patients who present this type of seborrheic dermatitis in order not to miss evidence which may be present on the genitals, palms, soles, nd mucous membranes (Figs 265, 266).

Macular Lues II and Tinea Versicolor.—Tinea versicolor is rather common parasitic

Fig. 208.

TINEA VERSICOLOR	MACULAR LUES II
Usually large patches and geographic areas with scattered peripheral islets.	Discrete macules, no large patches.
F wn yellow or brown tinge.	Pale pink, not yellow or brown.
Confluent tendency marked.	N confluence. Lesions discrete.
Scale fine, furfuraceous.	No scale.
Papular lesions very rare.	Some papular elevation, slight but definite, may be present.
Ringworm fungus easily found in scales on digestion with 20 per cent KOH.	No ringworm fungus.
No adenopathy or constitutional signs.	General adenopathy and concomitant signs.
Months or years duration.	

Fig. 209

PROBABLE CHANCRE OF THE GUM, SATELLITE BUBO TREATED AS PHLEGMONOUS, HEADACHES MISINTERPRETED. SECONDARY ERUPTION ALMOST UNRECOGNIZED BECAUSE OF ARTIFICIAL LIGHT. HYMEN INTACT. FIANCÉ INFECTED BY ATTEMPTED FORCED COITUS.

Female, aged eighteen, school-teacher

6/21/16 Entered Clinic.
Chief Complaint. Infection right side of neck.
Thickening right lower jaw two weeks' duration.
Crown removed by dentist.
Adenitis incised and drained.
Rx shows abscess in front of first right lower molar.
Lesion described as swelling of jaw 4 inches in diameter.
8/19/16 Quinsy (?) and drainage of abscessed gland in neck.
10/7/16 Severe headaches began three weeks ago. Much orse at night. Slight delirium. Slight anemia. Hemoglobin 68 per cent.
Blood W ssermann reaction negative.
General examination negative.
Given KI and iron and observation d-vised.

1/5/17 Sent to Dermatologic Section for Acne. Seen by artificial light. Diagnosis of seborrheic dermatitis was made. In Carrying Through the Routine Complete Dermatologic Examination, Even Though It Seemed Unnecessary three large condylomata were found between the labial folds. Inspection of the skin by daylight showed faint macular eruption probably involuting, ith few grouped follicular lesions on seborrheic base.
Blood Wassermann reaction strongly positive.
Three weeks before, the patient fiancé had attempted forced coitus. On examination the hymen as intact. Patient warned t notify fiancé of danger of infection. Two months later the patient received letter from fiancé stating that he had developed signs of infection and was about to begin treatment.

Discussion

1. It is difficult to decid from the incomplet histories taken by various departments whether the swelling of the jaw with the associated phlegmon was the primary lesion ith its satellit bubo or whether the quinsy with "abscessed gland" marked the onset of the syphilitic infection.

2. Th misinterpretation of the satellite bubo of the headaches, and of the character of the eruption when seen by artificial light will illustrate how easily an extragenital infection, or any syphilitic infection in woman, may escape recognition even by well-trained clinicians.

3. It is impossible to decid th source of this patient's infection—whether from dental instruments, from utensils, or from personal intimate contact. The personality of the patient excluded perversions.

4. The time intervals suggest that the early secondary eruption may have been overlooked in the examination of 10/7/16. It was involuting on 1/5/17.

5. This case further illustrates how complet must be the dermatosyphilologic examination if mistakes are to be voided and how inexcusably inadequat are the routine office examinations with exposure only of such portions of the body are complained of frequently under unsatisfactory lighting conditions.

6. The infection of th fiancé is point of unusual interest. An intact hymen is not necessarily evidence that an infection extragenital. The time relations in this case make the oma the source of the man infection.

Fig. 270.

PITYRIASIS ROSEA MACULOPAPULAR TYPE	MACULOPAPULAR LUES II
Fawn yellow color over pink.	Pink color
Long axis of macules and papules in lines of cleavage.	Axial tendency absent or slight.
Slight crinkle and suggestion of annular lesions.	May be slight atrophic crinkling, but it follows the lesions.
Retiform network and some confluence.	Macules and papules remain discrete.
Pseudovesicles occasionally seen (rare)	No vesiculation.
Prodromal lesion (primitive plaque) may be found.	No prodromal lesion.
No mucous membrane lesions.	Mucosal and other concomitant lesions.
Limited to trunk and upper arms.	Look for palmar papules.
N general adenopathy or constitutional symptoms.	Often general adenopathy

Fig. 271

MACULO-ANESTHETIC LEPRA	MACULAR LUES II
Common on body	None on face (except mottled chin"), rare on extremities.
Lesions tend to be large, coarse, obvious, blotchy and scattered.	Lesions small, faint, close-set.
Tend to deeper brownish-pink or purplish.	Faint pale pink.
Definit infiltration common.	Slight edema, but palpable infiltration (except in definite papules) rare.
Persistent, lasting months or years.	More rapid evolution, over in one to three months.
Sensory changes and evidence of trauma on anesthetic parts.	N sensory changes.
Enlarged and painless ulnar nerves.	N ulnar nerve changes.
Syringomyelic hands.	No changes in hands.
Trophic disturbances and bullae.	N trophic disturbances.
Nasal smear shows acid-fast intracellular Hansen bacilli.	Nasal smear negative.
No mucous or genital lesions.	Concomitant mucous and genital lesions.

Fig. 272.

MEASLES	MACULAR LUES II
Prodrome of fever coryza, bronchitis, photophobia, and conjunctivitis.	No systemic symptoms unless fever typhoid type, and sore throat.
Koplik spots on mucous membranes, small punctate bright red with minute blue centers.	No Koplik spots; they do not resemble mucous lesions.
Adult patients usually very sick.	Adults usually little affected, up and around.
Eruption maculopapular with confluent tendency forming crescents.	Macules discrete.
Appears first on face, abundant in that region.	None on face unless few papules or "mottled chin
Eruption develops rapidly; two to three days.	Eruption evolves slowly matter of two to three weeks.
Lesions florid to dark red nd even hemorrhagic.	Lesions pale pink, never hemorrhagic.
Desquamation fine, furfuraceous, begins in five to seven days.	No desquamation.
Course run in tw eeks.	Course run in four eeks to three months.

disease of the skin, due to ringworm fungus, *Microsporon furfur* The lesions suggest seborrheic dermatitis more than macular eruption. The sites of predilection are the thorax, shoulders, and back.

Pityriasis Rosea and Maculopapular Lues II.—Pityriasis rosea is an eruptive disease of the skin, of unknown cause characterized in about 27 per cent of the cases by the appearance of

Fig. 273.

ROSE SPOTS OF TYPHOID FEVER	MACULAR LUES II
Usually sparse punctate, sharply defined, and scattered.	Lesions usually abundant, more closely set, resembling marbling of the skin (cutis marmorata).
Color lively pink or even red. Often darker central, even hemorrhagic point.	Pale pink, often scarcely visible, uniform, fades into skin.
Most abundant over abdomen.	Most abundant, flanks, shoulder back.
No other cutaneous or mucosal lesions.	Look for mouth, genital, palmar plantar lesions, and alopecia.

Fig. 274.

MACULAR TOXIC ERYTHEMA	MACULAR LUES II
Angina apt to be cut severe streptococcal type, much edema, even membrane Strawberry pharynx.	Angina milder more chronic accompanied by mucous lesions in mouth.
Fever high, patient apt to be quite sick.	Fever slight or septic, patient seldom ill.
Eruption abundant, rather florid, tends to confluence more abundant on the extremities, suggest measles in color may be hemorrhagic or punctate, and scarlatiniform.	Eruption usually scanty pale, confluence rare. Most abundant flank, shoulders never purpuric, punctate, or scarlatiniform.
Course short and acute two to seven days.	Course indolent prolonged, matter of weeks.
Desquamation occasionally	No desquamation (unless scaling of papules)
No general adenopathy	General adenopathy frequent.

Fig. 275.—The papular phase of a maculopapular syphilid, best seen in the anterior axilla and flank.

prodromal lesion, followed after an interval of five to fifteen days by an outbreak of similar lesions over the trunk and upper portions of the extremities. The prodromal lesion is spoken of as the "primitive plaque." It is usually an oval or ringed patch with a slightly raised faintly scaling

A B

Fig. 276.—A, Small papular syphilid. Some of the lesions are follicular. Slight scaling produces the whitish sheen on the penis. B, Lesions in A, natural size.

Fig. 277.—"Slow smallpox." A papular secondary syphilid of the palms, diagnosed variola. Note the collarets of scales about many of the lesions. For differential diagnosis see Fig. 294.

pink border and a fawn-colored slightly scaling center The annular lesions of the subsequent eruption resemble it to some extent, but are smaller The typical annular lesion of pityriasis rosea

Fig. 278.—A shotty papular syphilid of the soles. Such lesion is almost diagnostic except during outbreaks of variola.

Fig 279—Scattered papular syphilid of the soles, the only lesions presented by the patient, and nearly overlooked through failure to remove the shoes and stockings in preparing for examination.

can scarcely be mistaken for anything else by one who has once seen it, the differential difficulties being confined largely to the aberrant types. The pink border and the peculiar cigaret-paper crinkle and fawn color of the center are very characteristic (Figs. 263, 290-292). Pityriasis rosea

lesions have peculiar trick of rranging themselves ith their long axes in the lines of cleavage of the skin, especially over the upper back and flanks, which is sometimes almost sufficient for diagnosis. The differential importance of this eruption is considerable for it is repeated beto oc

Fig. 290 —Typical papular palmar syphilid associated with preponderantly macular eruption.

Fig. 291 —A typical corymbose papular lesion. For other corymbose eruptions see Figs. 330, 431

casionally accompanied by false positive blood Wassermann reactions, by the older technics, and may also occur in patients ho have had syphilis, giving the impression of seronegative relapse. The condition has ide range of eruptive manifestations which bring it into differential

consideration repeatedly and highly typical forms may be quite puzzling t the inexperienced. The course of the eruption lasts bout six to ten weeks in the average case, and ends in spontaneous recovery There may be some itching but no associated general symptoms, or adenopathy

Macule-anesthetic Leprosy and Lues II.—Leprosy while not common disease is singularly often confused with syphilis. In fact, it wears the mask of syphilis more often than any other disease, in our experience and rarely escapes at least one diagnosis of syphilis before it comes t recognition in this country Part of the confusion arises from the frequency of false positive blood Wassermann reactions under the older technics, which has not yet been done way with by the modern serological procedures. Other aspect of the objective differentiation are dealt with under papular and nodular syphilids and alopecia. The nasal smear and the examination for sensory changes will always be useful check on the dermatological findings if even the slight est suspicion presents. Enlarged and insensitive ulnar nerves, enlargement of the nipples, and the bluish syringomyelic hands and traumatized feet, hands, and knees (anesthetic areas) should always be searched for The differential scheme here considered is that of the "leprous exanthem, but the macular lesion may occur late (Fig. 264).

Fig 291.

PSORIASIS	PAPULAR LUES II
Nearly always involves one or more of the following regions, scalp, elbows, knees.	Rarely affects elbow or knees and usually pustular in scalp.
Predilection for extensor surfaces.	Predilection, if any for flexors.
Polymorphic. Tendency to form large confluent patches and gyrat and geographic contours.	Lesions usually discrete one type
Eruption and elementary lesion usually florid red.	Lesions usually duller brownish red.
Scale bundant imbricated, silvery platelike less easily detached.	Scale scanty flakes off easily does not accumulate
No induration other tha that imparted by resistance of scale	Marked shotty induration.
On curetting off the scale and lightly abrading the surface of the papule minut multiple hemorrhagic points ppear representing the tops of the capillary loops	On curetting off the scale and abrading the papule diff se bleeding nd no visible capillary points are seen. Only serous exudat is obtained at times unless the abrasion is carried much deeper than in psoriasis.
Palmar and plantar lesions usually scale more abundantly No induration. Nail changes common.	Palmar and plantar lesions shotty slight peripheral collarette of scales, nail changes rare.
No scars	No scars in early syphilids, slight atrophy or scars in recurrent and lat lesions.

Measles and M cular Lues II.—It has been source of some surprise to us to not that this error is not so extremely infrequent. The cases which have seen merely express the low index of suspicion toward syphilis which still prev ils in verage practice An axiom hich ill aid in preventing confusion of syphilis with exanthemata is thi if an eruption is slow and takes eek or t t go through the changes which it should in twenty-four t forty-eight hours, take Wassermann test, nd look for syphilis.

Typhoid Fever and Macular Lues II.—While this confusion is not common, it none the less occurs. A patient, after several weeks in bed ith rose spot on the bdomen, and septic temperature and mental stat recovered and was leaving the hospital. He was seen by particularly alert man be passed through the hall, nd the slight lopecia of the sides of the scalp noted at glance The physician had the presence of mind t stop the patient and on further examination the syphilis as identified.

Macular Toxic Erythema and Macular Lues II.—Following streptococcal sore throats and tonsillitis, and occasionally after intestinal infections, macular eruption of an evanescent type may ppear hich may be cause of concern, though rarel source of actual error in diagnosis

Drug Eruptions and Macular Lues II.—The foregoing considerations (Fig 274) also pply t the large group of macular drug eruptions.

PAPULAR SYPHILIDS

Psoriasis and Papular Lues II.—This, fortunately is not common source of diagnostic error although psoriasis in syphilitic patient may t times present some puzzling features.

Fig. 283.

PITYRIASIS ROSEA, PAPULAR TYPE	PAPULAR LUES II
Rare on face and below elbows or knees.	Common on face.
No palmar or plantar lesions.	Palmar and plantar lesions frequent.
Axial arrangement of papules in lines of cleavage.	No axial arrangement.
No induration.	Definite deep shotty induration.
Annular lesions common in mixed types with fawn-colored cigarette-paper crinkled centers and pink borders.	Rarely any annular lesions. All one or all the other (unless in negroes).
Prodromal primitive plaque.	No prodromal lesion.
No mucosal or condylomatous lesions.	Mucosal and condylomatous lesions frequent.
No genital lesions.	Genital lesions frequent.
No general adenopathy.	General adenopathy frequent.

Fig. 284.

ARSENICAL KERATOSES	PALMAR PAPULAR LUES II
Diffuse keratotic thickening often present.	Sometimes diffuse infiltration but little keratosis. Fleshy deep induration or edema.
Miliary hard, horny raised papules.	Larger flat indurated thickened papules, but seldom really horny (exceptions in lues cornée, see Fig. 841).
No scale.	Peripheral collarette of scale often present.
Crateriform depression in many papules with central horny point or spicule.	Surface smooth, usually no pit or depression, no spicule.
No arciform configuration.	Marked tendency to arciform configuration in late lesions.

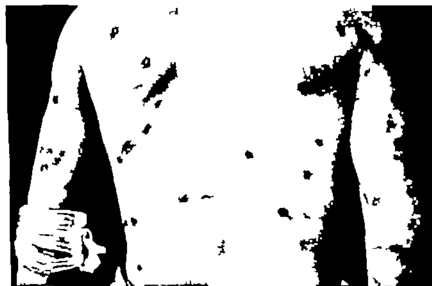

Fig. 285.—The psoriasiform secondary syphilid. Note the appearance of induration and the scanty scale as compared with Fig. 286. For differential diagnosis see Fig. 282.

Pityriasis Rosea, Papular Type, and Papular Lues II.—Most eruptions of pityriasis rosea involve both papular and annular elements, but one occasionally sees florid papular type which is quite difficult at first glance to distinguish from syphilid. The primitive plaque may be entirely absent in these cases. While the distribution of pityriasis rosea rarely involves the face,

Fig. 286 —Lesions of psoriasis, showing the greater superficiality and more conspicuous scale (See also Figs. 487 488.)

the lesions may occur on the face in children and in particularly severe outbreaks in adults (Fig. 290). I certain epidemics of pityriasis rosea the type form of the eruption may vary considerably from those described For example even i the adult, many of the lesions may appear on the face and neck, or large proportion of them may appear below the elbow and knees, leaving only an

Fig 287 —Papular psoriasis of the soles.

occasional though often typical lesion on the trunk to identify the process. I such cases axial distribution becomes unimportant, and the lack of induration, the fawn and pink color the cigaret-paper scale and annular form of occasional lesions, with the history of prodromal lesion, become the chief differential criteria. It must not be forgotten, moreover that pityriasis rosea may occur in patient ith syphilis.

Variola and Papular Lues II.—A severe papular syphilid may suggest quite decidedly the papular stage of variola, and in times of epidemic serious mistakes may result from the isolation of such persons in pest houses. The resemblance of the papular syphilid to variola is less marked

Fig 298.—Papular psoriasis of the rists and palms. The pitting of the nails often assists in diagnosis (see Fig. 299)

than is that of the pustular syphilid, but the following differentiation is important. In case of doubt it is advisable t isolat the patient pending Wassermann test and observation of the evolution of the lesions, but under no circumstances should such patient be placed among other

Fig 299.—The fingernails in psoriasis. The pitting of the nails of the middle and little fingers is especially characteristic

variola patients in smallpox hospital until the matter is decided. It is equally essential to keep under control the patient with varioliform syphilid for t least the week quired for full observation (Fig 332)

Pityriasis Lichenoides Chronica and Papular Lues II.—While this is comparatively rare condition, some cases may so perfectly mimic syphilis as to deceive even experts. Such case is shown in Fig 293. The cause of the group of dermatoses of which this condition is a member (parapsoriasis) is unknown. *They are all highly resistant to treatment of any kind and do not* respond t treatment for syphilis. The residual pigmentation hich follows the lesions may produce excellent imitations of syphilitic leukoderma (Fig 293) The Habermann syndrome (pityriasis lichenoides et varioliformis acuta) also strikingly resembles a papular varioliform syphilid, but is quit rare.

Lichen Planus and Papular Lues II.—Lichen planus is a cutaneous disease which, in some respects at least, bears striking resemblance to secondary syphilis. The distribution of the lesions is comparable t that of syphilis—over the trunk, arms and legs, in the mouth, and on the genitalia. The eruptions are papular and there is lichenoid syphilid which imitates them almost to

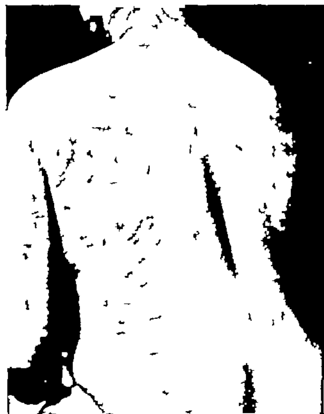

Fig. 290 —Papular pityriasis rosea. Not the tendency to distribution i the lines of cleavage of the skin. For differential diagnosis see Fig 293.

perfection. Annular lesions are not uncommon and upon the genitalia may be highly deceptive Lichen planus respond therapeutically t both arsenic (other than arsphenamine) and mercury and to the latter drug by mouth in doses and at rat which is not unl ke the response in syphilis, though somewhat slower Lichen planus gives rise in rare cases t follicular eruption, and at times to lesions on the palms and soles and bout the ankles hich suggest the keratodermic syphilids. W have even seen hypertrophic lichen planus on the penis simulat rather dry and verrucous condyloma (Fig. 302). There is even, as we have said, cutaneous reaction to arsphenamine which imitates lichen planus. It is evident, therefore that the physician ho is likely t deal much ith syphilis should familiarize himself with the eruptions of lichen planus, for w have seen it being burned t the treatment room under diagnosis of serologically negative syphilis in clinics of considerable size and have seen numerous vexations and embarrassing blunders from misdiagnosis in privat practice. A large part of the diagnosi of lichen planus under all circumstances rests on the identification of the elementary lesion, hich, fortunately is very

Fig. 291.—Psoriasis (elbow) and pityriasis rosea in the same patient.

Fig. 292.—Close-up view of typical lesions of the annular type of pityriasis rosea showing the cigaret-paper crinkle and scaling center. The peripheral portion of the lesion is pink, the center fawn colored.

characteristic, and which can usually be found about the wrists, over the shoulders, or on the forearms. The condition differs sharply from syphilid in being intensely pruritic, and much scratching usually results, with the development of characteristic papules in the scratch marks. Further

Fig 293.—Arsenical keratoses, unusually abundant. For differential diagnosis see Fig. 284.

differential considerations involving lichen planus are discussed under genital and mucosal lesions (Figs. 392, 393, and Chapter XV) There is, moreover lichen planus-like eruption occurring under arsphenamine treatment (p 422) which may cause confusion if misdiagnosed as syphilitic relapse (perhaps seronegative)

Fig 294.

VARIOLA (PAPULAR STAGE)	PAPULAR LUES II
Epidemic or exposure history	Not epidemic.
Sharp febrile prodrome with high fever backache, etc subsiding just before eruption ppears.	No brupt febrile prodrome or afebrile interval Fever and backache if present accompany lesions from the start, and persist.
Eruption rapid in onset, first lesions on face and wrists.	Eruption more gradual in onset, scattered more over face nd trunk.
Crop of lesions much al ke i age, size and shape	Lesions all ages, more variable in shape
Papular stage quickly passed, two to three days observation shows vesicular and pustular stage.	Papule slowly increased in size with little change in morphology Scale not crust, appears lat in course.
Areola bout trunk lesions.	Indolent, no areolæ.
Palmar and planta lesions may be hemorrhagic	Palmar and plantar lesions not hemorrhagic.
Mouth lesions acute, elevated, excoriated papules.	Mouth nd genital lesions indolent erosion.
	Concomitant evidence of syphilis. Isolate hile in doubt.

The Papulonecrotic T berculid and Lues II.—The differential diagnosis of tuberculids and syphilid is considered from the general standpoint in connection ith the landmarks of both diseases on the skin (Figs 351–357) It depends primarily upon the recognition of the essential lesion of the papulonecrotic tuberculid, hich is papule or in the earliest stages of its development, deep hemorrhagic vesicle that later develops necrotic central plug The plug hardens, and on separation leaves central pit, which later becomes the st of varioliform scar The

two tuberculids most likely to be confused with the papular syphilid are the papulonecrotic tuberculid of the face and that of the fingers. The former spoken of by some as acnitis, is illustrated in Figs. 303, 361 and the latter called folliclis, is shown in Figs. 312, A, B. Some morpho-

Fig. 295.—Pityriasis lichenoides chronica (Juliusberg) rather rare eruption easily confused at first with secondary syphilis. The dark macules in the picture are brownish-red papules, copper-colored spots, and pigmentary remains. For differential diagnosis see Fig. 296. (Collection of Dr William Allen Pusey.)

logically typical acnitis is not tuberculid, but may respond t arsphenamine. It is not at all uncommon for papulonecrotic tuberculid of the face t be treated as syphilis, and if arsphenamine happens to be employed, as as noted in discussing nonspecific treatment effects, the response may seem to clinch the erroneous diagnosis (Fig. 361).

Fig. 296.

PITYRIASIS LICHENOIDES CHRONICA	PAPULAR LUES II
Generally exempts the face.	Face and trunk.
N palmar and plantar lesions.	P lmar and plantar lesions frequent.
Little on extremities below elbows and knees.	Lesions frequent below elbows and knees.
Elementary lesion flat papule, flush with the skin or slightly raised with shiny surface showing no signs of scale until stroked ith curet (invisible scale).	Scaling more abundant, loose and self-detaching.
No definite induration.	Definite shotty induration.
Lesions of all ages and stages of evolution from macule to pigment.	Lesions more crop-like and of uniform type.
Extreme chronicity and resistance to treatment.	Definite progression two to six months' course.

Folliclis is less often mistaken for syphilid than is acnitis. It is less conspicuous, less acute

Fig 297—Lichen planus in young athlet who, although Wassermann negative, was refused as volunteer for the army on the ground that he had syphilis. Note the annular lesions, most often found about the wrists. This patient thigh is shown in Fig 298 The eruption is of distinctly purplish color Lichen planus furnishes some of the most deceptive imitations of syphilis, nd, moreover clears up under arsenic (but not arsphenamine) nd mercury (see Fig 302)

Fig 298.—The typical elementary lesions of lichen planus on hich the differential diagnosis from syphilis often depends (see Fig. 302) Note the polygonal, flat shiny papules. The glint on the surface is produced by the reflection of light, for there is no scale

g 299 —Annular lesions with trophic scarring produced by chronic lichen planus on the leg An annular lesion can be seen near the ankle.

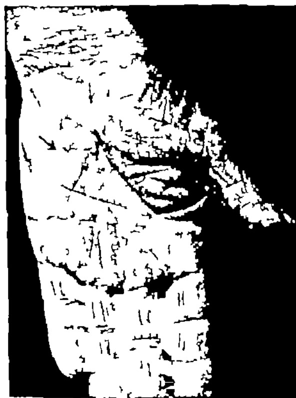

Fig. 300.—Lichen planus of the palm.

Fig. 501.—Lichen planus of the soles. This woman had received the diagnosis of syphilis. The diagnosis must be made on the remainder of the eruption and collateral evidence.

Fig. 502.

LICHEN PLANUS	PAPULAR LUES II
Rare on face, palms, and soles. Almost never occurs on scalp.	Relatively common on face, palms, soles, and may be pustular in scalp.
Characteristic elementary lesion (Fig. 498) flat polygonal papule with fatty or steely sheen or glint.	Elementary lesion an oval or rounded papule with rounded surface or hemisphere contour
No induration.	Marked deep induration.
Papular lesions small, 2 to 5 mm.	Papular lesions larger 5 to 15 mm.
Tendency to confluence.	Little or no tendency to confluence.
Specially characteristic lesions may be few	Lesions quite uniform in type.
Intense itching.	No itching or very slight (psoriasiform type)
Violaceous livid color with hyperpigmentation.	Brown red or "ham" color
Lesions appear in scratch marks.	No such tendency
Annular papular and umbilicated papular lesions not unusual. Small and with tendency to trophic change	Annular lesions, if present, larger
Pseudovesicles and even bullæ though rare.	No vesicles.
Palmar lesions small, translucent, sand-grain papules, no scale.	Palmar papules larger round, shotty flat and deep, with collarette of peripheral scales.

in many cases, and the lesions less suggestive. On the other hand, the resemblance between the horny papules of "lues cornée" and those of folliclis may be very striking, and differentiation on purely objective grounds very difficult (see Fig. 541).

Lesions of papulonecrotic tuberculid may occasionally be abundant enough about the extremities to suggest papular syphilid at first glance but the scars of crops of lesions usually assist in recognition, and the typical necrotic-centered lesion is, of course essential.

Fig. 303.—The papulonecrotic tuberculid of the face, usually confused with syphilis. See Fig. 304 for differential characteristics and Fig. 301 for another excellent example showing recovery under arsphenamine treatment. Note the necrotic-centered papules on the ear.

Fig 304

"ACNITIS"	PAPULAR LUES II
Essential lesion papule with dried necrotic central plug.	Essential lesion papule without central hard necrotic plugging (may be scaling, however)
Typical lesions often found on the lobe and concha of the ear	Ears not usually involved and no typical lesions.
Pitted, varioliform scars of former lesions or crops usually common.	No scars (unless excoriated or pustular).
Mucosa and genitalia not involved.	Mucosa and genitalia commonly involved.

Fig 305.

PAPULONECROTIC TUBERCULIDS OF THE FINGERS (FOLLICLIS)	PAPULAR LUES II
Typical tuberculid papule with dried necrotic central plug.	Flat or scaling papule, no necrosis.
Not indurated.	Indurated.
Tendency to appear on finger-tips and backs of hands.	Tendency to appear in palm and flexures of phalanges.
Deep vesicle t onset.	No vesicle.
Painful at onset (thorn in flesh sensation)	No pain.
White or depressed punctate scars.	No scars.

Chronic Urticaria and Papular Lues II.—T the dermatologist this seems at first thought an unlikely source of confusion, yet we have seen several striking examples. The annular papular syphilid seems especially to suggest urticaria to the inexperienced. The differential elements in the

Fig 506

CHRONIC URTICARIA	PAPULAR LUES II
Seldom appears on face.	Common on face.
May be accompanied by swelling of eyelids or lips, etc.	No edema of lids or lips.
Typical fresh wheals may be found with the papules, or even bullæ or vesicles in severe cases.	No wheals or vesicles.
Wheal pits with pressure (finger-nail)	Does not pit on finger-nail pressure. Deep induration instead.
Usually gyrate and annular groups and sometimes larger wheals.	Apt to adhere to one type of lesion at least in early cases.
Lesions evanescent, changing from hour to hour and day to day	Fixed eruption, not much change except gradual evolution.
Rose-bloom pink of urticaria.	More indolent and brownish in color
No scale	May be some scaling (psoriasiform)
Very itchy	Not itchy
No mucosal lesions unless edema.	Mucosal lesions common.
No genital lesions	Genital lesions common.

Fig 507.—An eruption of "raw-ham and copper-colored spots, which is not syphilid. This is the acquired form of urticaria pigmentosa in the adult. For differential diagnosis see Fig 508. On slapping or pinching, the spots become wheals.

Fig 508.

URTICARIA PIGMENTOSA	PAPULAR LUES II
Chronic and fixed. No evolution.	Evidence of evolution of crop of lesions.
No induration.	Marked induration.
No scale.	Older lesion and psoriasiform types present scale.
Gives wheal on slapping or pinching the individual lesion, or the pigmented macule or papule	No change on slapping or pinching except increased redness.
No palmar or plantar lesions.	Palmar and plantar lesions common.
No genital lesions.	Genital erosion common.
No mucosal lesions.	Mucous erosions and papules common.

Fig. 309.—A profuse eruption of papular sarcoid lesions in woman with syphilis. Confused with papular secondary syphilid. Diagnosis previously by biopsy

Fig. 310.—A papular syphilid of the face closely resembling nodular leprosy (Courtesy of Drs. Fordyce and Wise.)

Fig. 311.—Nodular lepra of the face. The lesion as accompanied by papular syphilid hich disappeared under treatment, leaving the leprous lesions unaffected. Note the leprous ulcer of the tongue. (Courtesy of Drs. Fordyce and Wise.)

eruption as such, apart from concomitant evidence of the presence or absence of syphilis, are given in Fig. 306.

A variety of urticaria known as urticaria pigmentosa, especially in the adult, because of its production of copper-colored spots, seems to be confused ith papular syphilids. The differential table (Fig. 306) applies t the adult (Fig. 307) and infantile (Fig. 706) types.

Nodular Lepra and Papular Lues II.—The papular lesions of nodular or mixed type of lepra may assist in the frequent confusion of this disease with syphilis. This must be especially

Fig. 312.—Papular eruption of leprosy simulating secondary syphilid (Collection of Drs Fordyce and Wise.)

Fig. 313.—Mycosis fungoides resembling leprosy and the papular infiltrative syphilid. (Courtesy of Drs. Fordyce and Wise.)

borne in mind because of the possibility of biological false positives with the Wassermann reaction in this disease (see Chapter IV) The leprous papular eruption especially when confined largely to the face, just before the development of the diffuse infiltration or leonine facies, may when

accompanied by alopecia due to infiltration of the eyebrows and scalp, create picture which at first glance defies the expert. In considering this differentiation Fig. 488 should be consulted in

Fig. 314.

NODULAR LEPRA	PAPULAR LUES II
Nodules larger coarser deeper less sharply defined.	Papules smaller more superficial and distinct, though indurated.
Infiltrated plaques or diffuse thickening common.	Confluence unusual No diffuse infiltration.
Very slow evolution—months or years.	Comparatively rapid evolution—weeks.
Nerve changes (mixed type)	No nerve changes.
Buccal lesions rare.	Buccal lesions common.
Cicatricial ulcerative changes.	No cicatricial ulcerative changes.
Positive nasal smear (Hansen)	No lepra bacilli in nasal smear
Lepra bacilli in tissue or lymph.	*Spirochete pallida*, but no lepra bacilli.
N palmar lesions.	Palmar lesions common.
No genital lesions.	Genital lesions common.

addition to the following. The neurological changes if present assist materially in the differentiation (Figs. 310–312, 314)

Annular Papular Syphilids

Dermatophytosis and Annular Lues II.—"Ringworm seems to be common pitfall in the diagnosis of late annular syphilids, but it may also be very important factor in early syphilids, in which the comparative sparseness of the lesions and their predilection for the face tend to deceive the inexperienced. The annular syphilid is papule, and as such has the raised border and indurated feel of ring-shaped infiltration. The differential elements are given in Fig. 315

This differentiation does not, of course, include the pustular or agminate follicular trichophytoses and the kerionis or macaroon-like trichophytic granuloma, which are not likely to be

Fig 315

DERMATOPHYTOSIS	ANNULAR LUES II
Lesions apt to be solitary or geographic group.	May be solitary but more apt to be several and scattered.
Superficial, no induration.	Definite deep cord-like induration, though perhaps not marked.
Peripheral satellites, evidence of auto-inoculation or extension about large lesion.	Satellites unusual (unless in corymbose configurations)
Vesicles and pustules (may be minute) recognizable in border with hand lens.	N vesicles or pustules.
Quit actively inflammatory as rule	Usually indolent, dull color.
Ringworm fungus detectable by microscopic examination of scales treated with KOH solution (20 per cent.)	N ringworm fungus in scales.
More inclined to scale.	More likely to be indurated, smooth, non-scaling.

confused with the annular syphilids. It does not include, furthermore, the trichophytoses of the scalp, which produce patchy alopecia in childhood, and in the case of the scarring ringworm, favus, permanent cicatricial alopecia. The tendency of the arsphenamines in certain patients to cause the flare-up or extension of dermatophytic lesions, with the appearance of ringed erup-

Fig. 316.

ANNULAR SEBORRHEIC DERMATITIS	ANNULAR LUES II
Localizes in seborrheic area face, presternal, interscapular regions.	Except for the face, no special localization.
Superficial, no induration.	Deep induration.
Surface may show minute vesicles.	No vesicles.
Distinct tendency to follicular involvement (puncta)	Surface tends to be smooth, shiny slightly scaling, and translucent.
Scales yellowish, oily	Scales (if no concomitant seborrhea) dry grayish.
No genital lesions.	Common on genitalia, especially scrotum.
No mouth lesions.	May be concomitant mouth lesions.

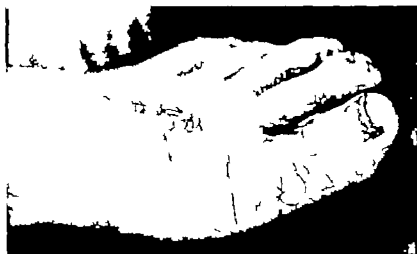

Fig. 317 —A moist secondary syphilid (eroded papule) resembling dermatophytosis between the toes. (Patient of Dr Herman Beerman.) This is the type of case reported by Thomas and Bluefarb (1940) as an occasional source of diagnostic error

Fig. 318.—Annular secondary syphilid of the face. Note the dryness, the scale the indolence all of which distinguish it from impetigo (Fig. 319) For differential diagnosis from ringworm see Fig. 316.

Fig. 319.—A characteristic impetigo contagiosa of the face. For differential diagnosis see Fig. 322.

Fig. 320.—Annular syphilid of the arms. (Collection of Dr. F. G. Harris.)

Fig. 321.—An annular papular type of recurrent syphilid. This woman's original secondary eruption was apparently macular and was called measles. This eruption was diagnosed "chronic hives." For differential diagnosis see Figs. 306, 308.

Fig. 322.

IMPETIGO CONTAGIOSA	ANNULAR LUES II
Face and fingers favorite sites.	Face, extremities, trunk.
Superficial, no induration.	Definite induration.
Moist, crusted, with areola. Often bullous margin. Ca be rubbed off, leaving an oozing surface	Dry no crust, occasionally slight scale In the skin, not on it.
Actively inflammatory bright red, yellowish or reddish crusts.	Very indolent. F wn pink t brownish red.
Rapidly progressive, day to day	Little change in week or more.
In hairy regions especially superficial pustules may be present.	No pustulation.
Polycyclic border geographic contours on extension.	Usually individual ares and rings.
Itches and burns.	No symptoms.

Fig. 323.

PITYRIASIS ROSEA (Annular Type)	ANNULAR LUES II
Usually abundant, but not always.	Rarely profuse (except in negroes)
Often confluent over hips.	Lesions usually discrete.
Rare on face.	More common on the face.
Typical lesion an oval patch with pink superficial slightly raised scaling border, cigarette-paper crinkled center	Typical lesion a ring with firm palpable indurated border yellowish to brownish dull pink color Slight scale, center simply slightly scaling or normal.
Axial arrangement in cleavage lines.	No axial arrangement, though occasionally a suggestion of it in lesions below the scapula.
Premonitory primitive lesion often found.	N premonitory lesion.
Pseudovesicles may occur	N vesicles.
No mouth lesions.	May have mouth lesions.
No genital lesions.	Common on the penis and scrotum especially

Fig. 324

ANNULAR LICHEN PLANUS	ANNULAR LUES II
Rare on the face.	Common on the face.
Rings small (0 5 t 2 cm)	Rings larger (2 to 7 cm.)
Typical papules, flat, angular superficial and shiny may be found. Rings often composed of such lesions.	If ring is composed of papules, the individual units are larger rounded, deeper indurated.
Color violaceous with brownish tinge	Color paler yellowish to brownish pink.
May be marked trophy t sites of involuting lesions.	Little or no trophy
Lichen planus lesions in the mouth (silvery retiform net ork)	Annular papular or mucous erosive lesions in the mouth.
Lichen planus lesions on genitalia (see Figs. 393, 420)	Syphilitic lesions on genitalia (see Figs 416, 417 418)

those in the flexures and on the body must be borne in mind as an element of confusion with syphilitic annular eruptions and cutaneous relapses. Bismuth is also described as responsible for an annular pityriasis rosea-like eruption (Chapter VI)

Annular Seborrheic Dermatitis and Annular Lues II.—This eruption may at times cause some annoyance as a source of error especially in persons with marked and obvious seborrhea

or oily skin (Fig. 490). In general, annular syphilids are more conspicuous and obviously out of the ordinary than are the annular lesions of seborrheic dermatitis. The variety of seborrheic der-

Fig. 285.—Characteristic atrophic remains of annular lesions in lichen planus on the thigh For details of this case see Fig. 287

Fig. 286.

ERYTHEMA MULTIFORME (Iris Type)	ANNULAR LUES II
Localization to the extremities, especially the backs of the hands.	Localizes on face and trunk. Rare on hands.
Mucous membranes severely involved. Extensive bullous lesions and erosions. Lips livid.	Mucous lesions apt to be few and indolent.
Marked fetor	No fetor
Elementary lesion, wheal-like ring with central bulla.	Ring only. May be double, however. Central normal skin or slight scale.
Dark red or bluish-red color in concentric rings.	Indolent pinkish-yellow or brownish-red color
Large lesions may be urticarial or bullous and become denuded and exudative.	No bullae or scale.
Desquamates on involution if severe, but acute lesion rarely scales.	Slight scaling on fully developed lesion.

Fig. 287

GRANULOMA ANNULARE	ANNULAR LUES II
Rare lesion, usually solitary	Not a common syphilid.
Usually occurs on hands, face, neck, and may appear on trunk and extremities.	Unusual on the hands.
Usually non-inflammatory	More inflammatory
Deep papular arciform infiltrates in cutis.	Usually more superficial, though infiltrated and firm.
Chronic and of long duration.	Runs a more rapid course.
No other evidence of syphilis.	Concomitant evidence of syphilis
Distinctive histologic picture.	Histology that of syphilis.

matitis described as seborrhea petaloides, while an unusual one, may be quite deceptive on purely objective grounds

Impetigo Contagiosa and Annular Lues II.—This is the common superficial streptococcic or staphylococcic infection of the skin characterized by an eczematous oozing seropurulent exudat

Fig. 328.—The grouped follicular secondary syphilid. A magnification of these lesions is shown in Fig. 329.

Fig. 329.—Enlargement of the macular-follicular lesions in Fig. 328. Note the papular accentuation of the follicle mouths, the grouping, and the combination of erythema and hyperpigmentation in the groups.

from   circular patch of deep red inflammatory reaction with the formation of crusts. Peripheral extension in rings from an involuting center is frequent. It may be differentiated from an annular syphilid by the considerations shown in Fig. [illegible].

Pityriasis Rosea, Annular Types, and Annular Lues II.—Compare this differentiation under macular and papular types of eruption. The identification of typical elementary lesions and axial arrangement are important features (Figs. 290, 292, 325)

Annular Lichen Planus and Annular Lues II.—*Lichen planus rarely produces profuse annular type of eruption.* On the other hand, groups of such lesions may occur about the wrists and on the back and thighs, which may be quite confusing. The annular lichen planus of the penis

Fig. 381.—A profuse follicular syphilid, showing disappearance of the grouping on the arms.

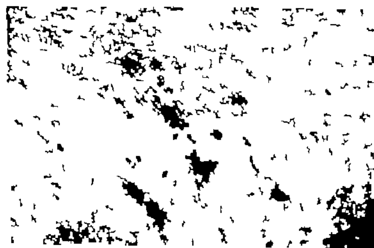

Fig. 380.—Magnification of a corymbose arrangement of papular-follicular secondary syphilid.

and scrotum, unless accompanied by mouth and other lesions, may puzzle the most expert (Figs. 299, 324, 325, 393, 410).

Erythema Multiforme (Iris Type) and Annular Lues II.—While erythema multiforme is, as a rule, a very acute affair, the chronic indolent types at times associated with a tuberculous diathesis, and the acute forms with mouth lesions, furnish the basis for some very serious errors in diagnosis. The response of erythema multiforme to arsphenamine increases the possibility of error (Figs. 366, 376–379).

Granuloma Annulare and Annular Papular Lues II.—The lesions of granuloma annulare, usually solitary and few in number are more apt to be confused with those of late syphilis than early We have, however seen multiple lesions in which the differential diagnosis required some study (Fig 572)

Chronic Urticaria and Annular Syphilids.—This differentiation is covered in Fig 306.

Fig. 332.

PERIFOLLICULAR SEBORRHEIC DERMATITIS	FOLLICULAR LUES II
Localized in seborrheic areas, sternum, and interscapular region. Rarely seen elsewhere.	Occurs in flank, ver abdomen and arms as well back.
Lesions not distinctly grouped. Large ir regular patches common.	Distinct small groups.
Definite dermatitis, with tendency to confluence of follicular lesions. Scaling and redness.	N dermatitis in the groups. Simply pigment. No confluence.
Follicles patulous and conspicuous, no real papule at follicle mouth.	Definite papule t follicle mouth.
Margin of patches pink, center yellowish pink.	No marginal differentiation of lesion.
A greasy yellowish plug may be present in the follicle mouth.	A definite papule with or without plug.
Thin yellowish oily scale.	Little or no scale.
Miliary vesicles or pustules may be found.	No vesicles or pustules unless in mixed follicular and pustular types.

Fig 333.—The perifollicular type of seborrheic dermatitis. Eruption confined largely to the back Note the confluent macular lesions on the upper flank.

FOLLICULAR SYPHILIDS

Perifollicular Seborrheic Dermatitis and Follicular Lues II.—Seborrheic dermatitis, among its polymorphous possibilities, embraces a type which may bear definite resemblance to follicular syphilid on hasty inspection. This is especially true of the macular follicular syphilid. Seborrheic dermatitis usually loses its initial follicular character early in its course, however and

Fig. 334.—The lichenoid dermatophytid simulating the grouped follicular secondary syphilid. The patient had an extensive ringworm of one leg.

assumes the confluent patchy dermatitic characteristics which render its differentiation from syphilids comparatively easy (Fig. 333).

The Lichenoid Dermatophytid and Follicular Lues II.—These lesions may at times be almost indistinguishable except by concomitant evidence of syphilis and therapeutic response. The dermatophytid, however is always secondary to a focus of ringworm infection, as the follicular tuberculid, called lichen scrofulosorum, is to a focus of tuberculosis. If a dermatophytic focus or lesion can be demonstrated, the presumption is in favor of a dermatophytid. The difficulties of

diagnosis are apparent from Fig. 334. The papules of the dermatophytids are more apt to be spinous than are those of the follicular syphilid, in which the essential lesion is more a perifollicular fleshy papule than a spinous plug. The groups of the dermatophytid tend to be larger and fewer in number. These are at best, however, only uncertain distinctions, and the entire case must at times rest on the demonstration of concomitant syphilis and the absence of ringworm focus.

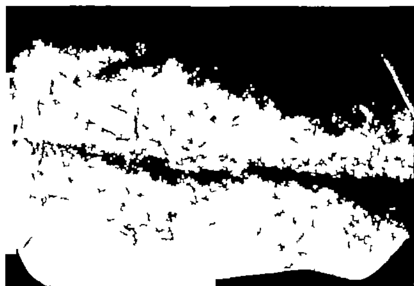

Fig. 336.—An extensive lichen scrofulosorum, simulating grouped follicular secondary syphilis.

Fig. 335.—Lichen scrofulosorum, accompanying tuberculous hydrarthrosis of the knees. For differential diagnosis see Fig. 337.

Lichen Scrofulosorum (Tuberculid) and Follicular Lues II.—This is at times an important differentiation, though a relatively rare one. The follicular tuberculid may like the dermatophytid be an accompaniment of a tuberculous focus, such as a joint involvement or a glandular lesion, and assist in the differentiation of the primary condition from syphilis (see Fig. 609). The principal points in the differentiation of the cutaneous lesion are given in Fig. 337.

Pityriasis Rubra Pilaris and Follicular Lues II.—While Devergie's disease is a comparative rarity, it at times presents a puzzling picture. The elementary lesion is a follicular papule which

as the disease progresses extends toward confluence with neighboring lesions, producing a diffuse dermatitis over considerable areas or the entire body. The lesions are first found on the neck and forearms, and the spinous plugging of the follicles on the dorsums of the fingers is quite characteristic (Fig. 338). Very extensive and acute follicular syphilids may, however, at times produce this picture.

Fig. 337

LICHEN SCROFULOSORUM	FOLLICULAR LUES II
Large nutmeg-grater or goose-flesh patches are more common than the smaller follicular groups in adults.	Small, closely set, widely disseminated groups of lesions.
Most abundant on abdomen and flank. No other types of generalized cutaneous lesion present.	Most abundant over back and extremities, and most typical on the back. Macular and papular lesions often present.
No alopecia.	Alopecia a common accompaniment.
Elementary lesion a yellow, almost flesh-colored papule.	Elementary lesion a pink or dull red papule. More active looking eruption.
Groups less pigmented than those of the *follicular syphilid.*	Groups more pigmented.
No genital lesions.	Genital or mucosal lesions may be present.
Concomitant signs of tuberculosis may be present.	Concomitant evidence *of* *casual* syphilis may be present.

Fig. 338.—Note the "plugging" of the follicles on the dorsums of the phalanges. This is characteristic of pityriasis rubra pilaris, not the follicular syphilid. See Fig. 339.

Keratosis Pilaris, Lichen Spinulosus, and Follicular Lues II.—Keratosis pilaris is a relatively common affection, essentially a follicular type of ichthyosis. It may vary in severity from a slight accentuation of the follicles on the extensor surfaces of the upper arms to a diffuse and extensive follicular nutmeg grater plugging of the follicles in the flanks and over considerable areas, especially on the extensor surfaces (Fig. 340).

Follicular Lichen Planus and Follicular Lues II.—This is a rare lichen planus lesion, but one which we have seen confused with syphilid. The eruption consists of scanty small groups of pap-

Fig. 339

PITYRIASIS RUBRA PILARIS	FOLLICULAR LUES II
Universal distribution, including face, neck, body and extremities.	Face free.
Large patches.	Small groups of 5 to 15 papules.
Coarse nutmeg-grater ppearance nd feel.	Comparatively fine
Spinous follicular horny plug conspicuous feature.	Papule at follicle mouth, seldom spinous plug.
Tendency t confluence of patches.	Patches remain discrete.
Dermatitis with scaling develops confluent patches and becomes general.	No dermatitis, no scaling.
Follicular plugging, backs of fingers.	Fingers rarely involved.
Very slow and chronic course.	Comparatively rapid course.

ules, 2 to 5 in the verage lesion, small and noninflammatory Associated lesions of lichen planus of other types are usually present and are essential for diagnosis (Fig. 340) The follicular lesions

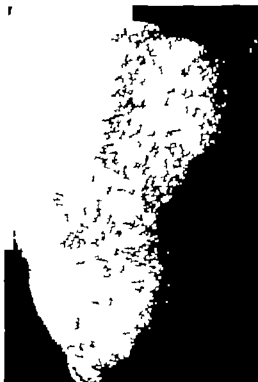

Fig 340.—Follicular lesions of the keratotic type over the right scapular region. These might represent keratosis pilaris, lichen spinulosus or follicular lichen planus (hich is the correct diagnosis). For differential tables see Figs. 341 342

of lues II are coarser more inflammatory the groups larger and better defined. Other signs of syphilis can usually be found in harmony with the stage of the disease

Fig. 341

KERATOSIS PILARIS	FOLLICULAR LUES II
Most pronounced on extensor surfaces and where follicles are normally prominent and abundant.	Most pronounced on back. Definitely recognizable even in softer parts of skin.
No grouping. May be some scattered large patches.	Definite small groups, rarely any confluence.
No hyperpigmentation.	Hyperpigmentation in the groups.
No alopecia.	Alopecia common accompaniment.
A spinous plug rather than follicular papule the essential lesion. Long duration, often since childhood.	A papule, not plug
One type of lesion, except for occasional miliary pustules.	Papular and macular secondary lesions may be coincident.
Often signs of concomitant ichthyosis (ichthyosis follicularis). Look for parchment palms and scaling forehead and shins.	Concomitant evidence of active syphilis.

Fig. 342.

LICHEN SPINULOSUS	FOLLICULAR LUES II
Slender spine projecting from the follicle mouth, the essential lesion.	No spine, or only slight horny plugging.
No papule or only slight elevation.	Papule definite.
Non-inflammatory	Mildly but definitely inflammatory
Grouping less conspicuous.	Grouping characteristic.
No pigmentation.	Hyperpigmentation of the groups.
No alopecia.	Alopecia common scalp lesion. Other lesions of active secondary syphilis.

Fig. 343.

ALOPECIA AREATA	SYPHILITIC ALOPECIA
Large patches few in number	Small patches, numerous, with some diffuse thinning.
Geographic outlines common (perfect circles, arcs)	Widely and evenly disseminated, giving moth-eaten appearance to sides of scalp.
Patches often completely bald.	Patches often not completely denuded
Sharp margin of almost normal hair density	Margins often fade into thinned hair

Fig. 344.

ALOPECIA OF CHRONIC ERYTHEMATOUS LUPUS	SYPHILITIC ALOPECIA
Few and scattered irregular patches of partial or total baldness.	Many small patches, usually smaller than those of lupus erythematosus.
Characteristic atrophy often with almost scarlike changes and telangiectasia.	No permanent atrophy or scarlike changes.
Permanent hair loss.	Usually temporary hair loss.
Signs of concomitant erythematous lupus.	Signs of concomitant early syphilis.
May show follicular plugs at borders.	No follicular plugs.

Fig. 345.—The typical moth-eaten alopecia of secondary syphilis. The process is often better seen at the sides and back of the head, where the hair is more closely clipped. A doubtful case is often made easily apparent by a close hair cut.

Fig. 346.—Typical alopecia areata. The patches are bald without scarring, and may contain sparse white hairs. The same process may involve the beard. This type of alopecia and alopecia totalis is sometimes seen in heredosyphilis, but there is no necessary connection.

Fig. 347.—A moth-eaten alopecia associated with acute disseminate erythematous lupus. Recovery. The alopecia of the scalp produced by the discoid (chronic) type of this disease is permanent, and leaves an atrophic scar due to destruction of the hair follicles.

Fig. 348.—Alopecia is much more difficult of identification in the woman than in the man, on account of the longer hair but it may be detected above the forehead, ears, and nape of the neck, and, as in this case, in the eyebrows.

Every clinician should learn to watch eyebrows. The clue to secondary syphilis, lepra, leukemia, may be found there. It is curious fact that picture of this kind, shown to an audience of men physicians is rarely identified; but when shown to an audience of women (nurses), the alopecia of the eyebrows is singled out at once.

It is justifiable to take blood Wassermann test on every patient who complains of the loss of any considerable amount of hair within short time.

This patient had no other signs of secondary syphilis except positive blood Wassermann reaction. She was first seen with large satellite bubo in the cervical region, huge tonsils, but no evidence of a primary lesion. The differential blood count, which showed successively 67.4, 79 and 63.5 per cent small mononuclears before treatment, led to suspicion of lymphatic leukemia. The count fell quickly to 43 per cent and the nodes subsided when treatment for syphilis was begun. Lymphatic leukemia rarely produces alopecia.

Syphilitic Alopecia

When it is borne in mind that the typical alopecia of syphilis has many of the characteristics of the follicular syphilid of the body minus the papular lesion and the hyperpigmentation, the alopecias, such as that of alopecia areata and of the trichophytoses, may be discarded almost at a glance. The alopecia produced by erythematous lupus of severe and extensive type, of which disseminate erythematous lupus is the best example, may be patchy and moth-eaten (Fig. 347) We have seen the permanent alopecia produced by discoid erythematous lupus that had been

A

B

Fig 349 —The alopecia of lepra (B) may be almost indistinguishable from that of secondary syphilis (A) Both patients had lost the outer thirds of the eyebrows. For differential diagnosis of syphilis and lepra see Fig 497

unusually abundant on the scalp deceive dermatological group until typical lesions appeared on other parts of the skin.

The alopecia of favus, the scar-producing ringworm infection, is coarsely patchy with distinct depressed scarring and permanent removal of hair in the affected areas. Active scutula of sulphur yellow color and mousy odor may be found around the old lesions. The alopecia of the juvenile ringworms is usually partial and involves the top of the head, with large oval or circular patches in which the hairs are in part gone, in part broken off or stunted and friable. Cicatricial alopecia also produces large patches comparatively few in number or solitary with an essential lesion of follicular pustular type and atrophic scarring

Fig 330 —A factitial alopecia produced by pulling the hair with the fingers. Neurotic patients can occasionally produce puzzling alopecias.

PUSTULAR SYPHILIDS

Variola (Pustular) and Pustular Lues II.—The essentials of this differentiation are considered under papular lues II. The course of variola is more likely to have revealed its true identity by

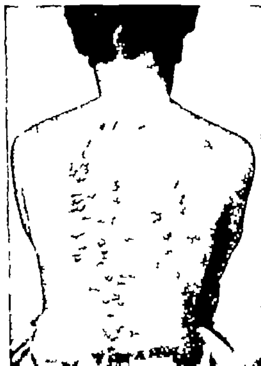

Fig. 331 —Small pustular syphilid in colored woman, of type apt to be confused with small-pox. For differential diagnosis see Fig 294 (Collection of D J F Schamberg.)

the time it has reached the pustular than when it is in the papular stage The variola pustule is prominent, elevated, highly inflammatory and on the trunk often presents an areola, while the syphilitic pustule is, on the other hand, flatter softer more indolent, crusts early and is less abundant, as rule than the variola lesion. Umbilication is quite distinctive of the variola pustule as compared with its practical absence in secondary syphilids. Variola lesions on the mucous membranes are easily distinguished. I cases occurring during epidemics of variola it is better

Fig 352 —An eruption of smallpox, mistaken for syphilis and admitted t venereal ward. For differential diagnosis see Fig. 294 (Collection of Dr J F Schamberg.)

Fig. 353 —A severe form of rupia in an unusually malignant syphilis. The lesions are of eighteen months duration and ere but l ttle affected by course of neoarsphenamine Recovery followed the use of arsphenamine ("606") and mercury rubs simultaneously For another illustration of rupia see Fig 89

Fig. 334.

ACNE CACHECTICORUM	PUSTULAR LUES II
Typical sequence of seborrhea, comedones, sebaceous retention cysts, deep inflammatory nodules, pustules and abscess formation, with scarring	No necessary association with comedones, sebaceous cysts, etc.
Limited to acne area of the body (face, back, chest)	Scattered over body
None in scalp.	Not uncommon in scalp.
Lesions markedly inflammatory often painful and furuncular	Lesions indolent, crusted papule, more in the skin itself less deep subcutaneous reaction.
Much pus, little crust.	Little pus, much crust
Scarring usually prominent in comparison with number of lesions.	Lesions prominent in comparison with small number of scars.

Fig. 335.

PYODERMA	PUSTULAR AND RUPIAL LUES II
Often associated with acne cachecticorum or follows variola.	No necessary association with acne
Scalp not often involved (except nape of neck).	Scalp often involved.
No definite configuration.	Grouped and gyrate configurations may be present.
Process mainly subcutaneous with under running soggy edges.	A cutaneous ulcer punched out.
Canalization with pus sinuses, multiple abscesses, etc.	No canalization, sinuses, or subcutaneous burrows.
Skin blue, soggy hemorrhagic, over considerable areas.	Skin only affected at site of lesion.
Little or no ulceration, and when present superficial and ecthymatous.	Ulcers rupial, deep, punched out, and granulating.
No crusts.	Crusting conspicuous.

Fig. 336.—Pyoderma and ecthyma following variola, and mistaken for syphilis. The canalization of the face with pus sinuses rarely occurs in syphilis. Compare Fig. 501 (late syphilid of the face)

to isolate the doubtful patient, especially if unvaccinated, though not with active cases of variola, pending decision, which should not rest wholly upon blood Wassermann report (Figs. 351 352).

Acne Cachecticorum and Pustular Lues II.—Acne cachecticorum is the severe acne of the back, based upon the typical comedone-papule-pustule-cyst sequence of acne vulgaris, but ex

Fig 357

ECTHYMA	PUSTULAR AND RUPIAL LUES II
Rarely involves scalp or face.	Common on scalp and face.
Superficial ulceration, border irregular shelving or undermined, fissured.	Rupial ulcer usually deep, punched out, granulating, round or oval.
Crusts flat, not so thick, suggest impetigo.	Crusts lamellated, thick, "oyster-shell, "turtle backed, or dished.
Follicular pustules, impetiginous patches, superficial blebs or flaccid pustules and sometimes furuncles, suggest pyogenic origin.	Lesions scattered, surrounding skin little affected, inflammatory areola and other signs of infection few
Background of ecthyma low resistance, diabetes, nephritis.	Background of syphilis; but Wassermann reaction may be negative.

aggerated often to huge proportions in persons who are markedly debilitated or who are the victims of some special though unknown predisposition. The lesions may or may not involve the face and chest (Figs. 354, 358)

Pyoderma and Pustular or Rupial Lues II.—The canalization of the infected skin by pus sinuses suggestive of scrofuloderma or even an actinomycotic infection may likewise in some

Fig. 358.—Scarring and active lesions of acne cachecticorum. (See Fig. 354)

cases suggest to the inexperienced, syphilid. This is particularly true of such lesions on the body Occasionally such nonspecific imitations of syphilids may prove highly puzzling as in Fig 356.

Ecthyma and Pustular Lues II.—Ecthyma is ulcerative form of pyogenic infection, essentially an ulcerative impetigo. It occurs in children, debilitated patients who are rendered susceptible by diabetes and nephritis, and those who are the victims of old age and bad hygiene.

Acne Scrofulosorum (Papulonecrotic Tuberculid of the Body) and Pustular Lues II.—The tuberculids of the body do not usually occur alone, but are apt to be accompanied by the more distinctive and easily recognized folliclis of the hands, the facial lesions of acnitis, or the leg lesions of erythema induratum. The differential diagnosis is sometimes extremely important, for patients with tuberculid may present partial positive blood Wassermann reaction with highly cholesterinized antigens, and the rapid response of the lesions to arsphenamine as we have seen, may suggest a syphilid. All adenopathies in which syphilis may be a factor regardless of their apparently tuberculous character should be searched for the scars of tuberculid. The acute extensive tuberculids of the body which may be confused with early syphilids usually occur in childhood, and are essentially miliary tuberculosis of the skin with grave prognosis (Fig. 359).

Acne Necrotica (Acne Varioliformis) and Pustular Lues II.—Acne necrotica is a papular eruption with the distribution of pustular seborrheic lesions and the morphology of papulonecrotic tuberculid. It usually involves the face, especially the forehead, the hair line, the presternal and the interscapular regions, but may occur in the scalp, and, in fact, in that situation may cause much confusion if the scarring be abundant. The scar is varioliform and were it not for its distribution would be very difficult to distinguish from that of a tuberculid or small pustular

Fig. 360

ACNE SCROFULOSORUM	PUSTULAR LUES II
Usually sparse and prone to localize on the extremities.	No pronounced tendency to localize on the extremities.
Chronic course, successive crops of lesions, seasonal incidence (spring and fall) large proportion of scars, few lesions.	More rapid course, more lesions, fewer scars, no seasonal history
Scars varioliform, scattered, no grouping or configuration.	Occasionally definite grouping and annular configurations.
Elementary lesion must be identified to make diagnosis [illegible] papule with definite necrotic center, dried central brown plug that can be picked out, leaving depression. Short vesicular no pustular stage.	Elementary lesion [illegible] pustule or papulopustule with crust and exudate, but not the typical necrotic central plug.
Removal of necrotic plug leaves conical pit.	Removal of crust leaves moist purulent ulcer
Other characteristic tuberculids such as erythema induratum.	Other lesions of syphilis.
Systemic tuberculosis, especially glandular	Systemic signs of syphilis.

syphilid. Groupings and configurations may be seen which are at times very confusing. The disease affects debilitated young or middle-aged women and men, and is of unknown etiology (possibly streptococcal). It does not respond distinctively to treatment for syphilis (Fig. 360)

DIFFERENTIAL DIAGNOSIS OF EARLY SYPHILIS OF THE MUCOSAE AND MUCOCUTANEOUS JUNCTIONS

The objective morphological differentiation of syphilis of the mucous surfaces is often more difficult than that of the skin, and resort to laboratory evidence, especially the darkfield, is much less confidently made. The mouth and the genitalia are, as has been seen, the habitat of spirochetes distinguished with difficulty from *Spirochaeta pallida*. Conditions such as moisture and secondary infection often reduce lesions to a nondescript uniformity in a short time, and make it imperative therefore that lesions of the mucous membranes be seen as early in their course as possible if their important characteristics,

Fig. 260.—Acne varioliformis (acne necrotica) showing the typical distribution to the face, especially the hair line and scalp margin, and to the back. The eruption may be more extensive. Note the necrotic-centered papules. The lesions are not crusted. For differential diagnosis see Fig. 263.

and still more their evolution are to be correctly interpreted. The mucous membranes may furnish during considerable periods of the disease and especially in relapsing cases, the only objective suspicion arousers and at the

same time the most dangerous lesions of the disease from the standpoint of transmission. The most painstaking habit of examining the mucosae and the anogenital region therefore is essential to the successful detection of a most

Fig. 361.—Severe papulonecrotic tuberculid of the face (acnitis), resembling pustular syphilid. This patient had been receiving mercury and iodide for supposed secondary syphilis, without effect.

Fig. 362.—Effect of seven arsphenamine injections (0.3 to 0.4 Gm.) on the tuberculid (acnitis) shown in Fig. 361.

Fig. 363.

ACNE NECROTICA (Acne varioliformis)	PUSTULAR LUES II
Confined to face, hair line, scalp, and presternal and interscapular regions except in rare severe cases.	Occurs on trunk as well and without marked predilection for sebhorrheic areas.
Typical lesion suggests tuberculid, not a syphilid—a necrotic-centered papule—but there may be some acneiform lesions.	No distinctive necrotic center to any lesions.
Lesions few and scattered at any one time.	More distinctly crop-like outbreak.
Scars white, varioliform, always present and abundant in comparison with number of active lesions.	Scars few or none in proportion to active lesions. Smaller lesions leave little scar.
Process very chronic.	Process more acute.
While below par, patients seldom show much constitutional effect.	Constitutional effects likely to be pronounced. Concomitant evidence of early syphilis.

important part of syphilis. The steps in the technic of examination of these regions, as given in Chapter II, should be strictly adhered to, and the possibility of syphilis be constantly kept in mind.

Some authors apply the term "acne agminata" to lesions of this type and do not regard them as tuberculids.

an indurated tonsil can sometimes be aspirated with a tonsil anesthetizing needle and lesions of the tongue and lip with a hypodermic needle Markedly

Fig. 308.—This lesion passed as hemorrhoid ith several physicians. When told to make darkfield examination one of our staff prepared for spurt of blood by putting a ligature in position around it before beginning t scrape. The lesion teemed with *Spirochaeta pallida*. Note the infiltration of the median raphe of the scrotum, the first point t suggest that the lesion was condyloma rather than hemorrhoid Ulcerating or eroded hemorrhoids with few symptoms should be regarded with suspicion.

Fig. 309.—Squamous cell epithelioma t the anus. Notice the sharply defined pearly border of the flat lesions. The process xtended 1½ inches into the anus. Such lesions may arise from leukoplakia. There no gross evidence of syphilis n thi case

enlarged lymph nodes associated with tonsillar lesions or lesions on the lip and tongue may be aspirated in accordance with the technic described in

Chapter III before a decision is made as to their character but smaller isolated nodes should not be disturbed if there is suspicion of carcinoma.

Streptococcal Angina and Syphilitic Angina.—Sore throat is one of the commonest accompaniments of the generalization of syphilitic infection, and frequently passes for a banal infection

Fig. 370.

CARCINOMA OF THE TONSIL	SYPHILIS OF THE TONSIL
Unilateral.	Lues I unilateral, Lues II bilateral
Tendency to crateriform destructive ulceration.	Infiltration and erosion rather than destruction.
A raised pearly or nodular border may be recognizable.	Border seldom raised or distinctive.
Much necrosis, confined to lesion.	Exudate but not much necrosis.
Stony hardness.	Elastic, but firm induration (Lues I)
Infiltration of pillars.	Pillars edematous rather than infiltrated.
May find Vincent flora.	May find *Spirocheta pallida*.
Lymph-nodes apt to be small or moderate in size in proportion to lesion.	Lymph-nodes apt to be large, even huge, in proportion to lesion.
Glands appear late	Glands appear early
No signs of secondary lesions on skin.	Secondaries may be present elsewhere
Get blood Wassermann test.	Get blood Wassermann test.
Specimen from the lesion shows carcinoma.	Specimen from the lesion shows chronic inflammation, but may suggest lymphoma or even lymphosarcoma and tuberculosis (no tubercles, however)

during an indefinite period until some conspicuous sign calls attention to its syphilitic origin. The taking of blood Wassermann tests more frequently if not routinely on sore throats, especially if they show evidence of chronicity and the habit of stripping patients for examination, even for so small a matter as a sore throat, would lead to the detection of a good deal of secondary syphilis in its incipiency The severe syphilitic angina and the streptococcal throat have the following differentiating points (Fig 371)

Fig. 371

STREPTOCOCCAL ANGINA	SYPHILITIC ANGINA
Acute onset, rapid course.	Slow onset, slow course.
Tonsillar at the outset, but may have only strawberry pharynx.	General angina, patches on pillars.
Membrane thick, furry yellowish or greenish.	Exudate grayish, thin, pellicle-like.
Much edema, especially palate and uvula.	Little edema Unilateral infiltrate in chancre and may be more edema.
Very angry red.	Redness only moderate.
Patient acutely ill, high fever fast pulse.	Patient loses weight but seldom high fever or fast pulse.
No cranial nerve palsies.	Third, seventh, and eighth nerve involvement may occur but rare.
No neuroretinitis or iritis.	Neuroretinitis and iritis to be looked for
Patient may be more ill than appearance of throat justifies.	Patient usually less ill than appearance of throat justifies
No mucous lesions in mouth.	Mucous lesions at commissures and lips, tongue, and pillars.
No papules on tongue.	May have papules on dorsum of tongue
No alopecia.	Look at hair and eyebrows.
May have acute toxic erythema, palms diffuse red or free.	May have roseola or papular syphilid, look for palmar papules.
No general adenopathy	General adenopathy including epitrochlears.
If not over in ten days, take repeated blood Wassermann tests.	Take more Wassermann tests "on suspicion.

Diphtheria and Syphilitic Angina.—This confusion is much too frequent cause of diagnostic error. If the habit of taking a blood serologic test on seeing "throat" could be made as common as that of taking culture, some tragic cases of extragenital and early genital infection, especially in women, could be earlier diagnosed. Suggestive objective differential points are as follows (Fig. 272)

Fig. 272.

DIPHTHERIA	SYPHILITIC ANGINA
Acute onset, rapid evolution.	Gradual onset, slow course.
White, grayish, or blackish necrotic membrane, embedded in the surface involved.	Pale gray exudat pellicle or pearly pseudomembrane over surface.
May slough, especially on tonsil.	Not likely to slough.
Bleeds on removal of pseudomembrane.	Oozes serum on removal of pellicle.
Edema, but not infiltration.	Brawny infiltration in Lues I.
Usually bilateral	Lues I unilateral.
Adenitis present, often tender acute, early and local.	Adenitis present, indolent, discrete, unilateral, not tender General in Lues II
Culture, Klebs-Löffler	Culture, negative, streptococcus, sometimes Vincent flora.
Toxic symptoms of diphtheria heart, peripheral neuritis, glossopharyngeal especially	Second, third, seventh, and eighth nerve involvement suspicious, but rare. Heart rarely shows disturbance clinically
N cutaneous lesions (except rare diphtheritic lesions)	Cutaneous signs of syphilis.
Headache not conspicuous.	Headache important symptom.
Antitoxin if in doubt, but take blood Wassermann test too.	Repeated blood Wassermann tests positive.
N lesions of syphilis elsewhere on mucosa.	Look for mucous patches under lips and in commissures, and papules on the tongue.

Fig. 273.

DIPHTHERIA. PAPULAR SYPHILID OVERLOOKED

Female, age fifty-nine, married, housewife.

Ambulance case arrived vomiting excruciating headache, paralysis of left side of face. Throat, membranous pharyngitis and tonsillitis.
No fever pulse nd heart normal.
Seen by medical man, who called laryngologist.
Seen by otolaryngologist, who took culture. House officer took Wassermann. Catheterized urine taken.
Neurologist called, reported probable luetic facial palsy Recommended lumbar puncture
Smears reported negative
SWR ### (second day)
Blood-pressure 170/90

Dermatologist called fourth day to see eruption on wrist. Found patient literally covered with maculopapular secondary syphilid, of seventeen days standing which had not been noted in any previous examination.
Liver and spleen enlarged.
History of vaginal discharge.
Husband, ge sixty-three examined ten days later found t have maculopapular Lues II and involuting primary lesion.
The home physician had given him some pills.
Wife's Spinal Fluid (end of first course)
W R. negative 4 c.c. Nonne positive
24 lymphocytes.

Discussion

1 The home physician was culpable in his management of the husband' case Mercury does not control infectiousness Mercury by mouth ha no place whatever in early syphilis except as an djunct.

2. Never too old for lues.

3 Never look at a bad throat without looking at the skin. A glance t the skin in this case ould have saved four days of special examinations.

4 Syphilitic pharyngitis and tonsillitis can present severe involvement diphtheria or Vincent angina.

Vincent's Angina and Syphilitic Angina.—Too much reliance on smears with ordinary stains, and failure to think of syphilis among the first possibilities in throat are the general causes of confusion here. Arsenicals should be voided in therapeutic tests because of the occasional effect on Vincent infections (Fig. 274).

Agranulocytic Angina and Syphilitic Angina.—The agranulocytic reaction to the arsenicals and bismuth as well as the idiopathic type and that with aplastic anemia from other causes, may be momentarily confused with severe syphilitic lesions of mouth and throat. The severe mouth and throat reactions to antisyphilitic drugs are described on page 403. Fig. 375 summarizes the differential points.

Erythema Multiforme and Syphilitic Angina.—Erythema multiforme of the iris type is an acute eruptive process usually incident upon bacterial invasion of the blood stream. The lesions

Fig. 374.

VINCENT'S ANGINA	SYPHILITIC ANGINA
Rapid, acute, destructive process.	Slower more indolent, less destructive.
Exudate yellow abundant.	Exudate pearly scant.
Marked necrosis.	Little necrosis, or none.
More inclined to involve soft palate and uvula.	Less inclined to involve soft palate and uvula.
Dorsum of tongue and commissures and lips free.	Look for mucous lesions and papules in these sites.
No cutaneous lesions.	Cutaneous lesions of syphilis may be present, but not necessarily. Look at palms and soles, axms, genitalia.
Don't trust darkfield to eliminate syphilis.	Aspirate the lesion if possible.
Adenopathy local.	Adenopathy likely to be both local and general.
Use the Wassermann test routinely	

on the skin range from purpuric macules through heals, usually annular and often with bullous centers (iris lesions—Fig. 378), to the deep subcutaneous tender infiltrations of nodose erythema. While hemorrhagic and petechial macular and papular syphilids have been described (Kalz 1940) they are extremely rare. Lesions on the mucous membranes of the mouth are common associates of the cutaneous picture, and in some instances may occur alone in repeated attacks before the final appearance of lesions on the body which identify the process. We have seen this disease so many times confused with syphilis, and even treated for it, that we have always laid much stress

Fig. 375.

AGRANULOCYTIC ANGINA	SYPHILITIC ANGINA
Evidences of mild or more commonly severe infection.	Rarely much constitutional reaction.
Ulcerations in pharynx or on tonsils.	Scant exudate—no ulceration.
May show deep gangrenous destruction.	Little or no necrosis.
Adenopathy usually absent.	Adenopathy present.
No exanthem (unless purpuria)	Usually concomitant cutaneous lesions.
Marked leukopenia.	Usually normal white count.
Rarity of granulocytes in differential count.	Differential blood count normal or slight lymphocytosis.
Frequently fatal termination.	Gradual involution of process—rapid with treatment.

on its differential diagnosis and have come to regard it as an unrecognized source of error for many physicians. In fact, the first case of erythema multiforme in our experience, whose diagnosis was confirmed by several subsequent years of observation, was, when first seen in 1912, in process of being demonstrated to a class of students as a syphilid clearing up under arsphenamine. The response of erythema multiforme to arsphenamine is often quite striking and accounts for the possibility of error from therapeutic tests begun with this drug.

The essential differential lesion of erythema multiforme is bulla, and once its characteristics

are firmly fixed in mind, and the practical exclusion of syphilis in the adult by the finding of bullae in the eruption is accepted, it becomes easy to differentiat erythema multiforme in the

Fig. 376.—A ruptured bulla of erythema multiforme on the lip. The condition is often taken for syphilis at first sight, especially if the lesions are for the time being limited to the mouth. It responds therapeutically t the administration of neoarsphenamine. In suspected cases examine the backs of the hands (see Fig. 378) For differential diagnosis see Fig. 380.

mouth from syphilis, provided complet examination of the patient is made (Fig. 380) Special attention should alw ys be paid to the backs of the hands, on which the characteristic iris lesions

Fig. 377.—The mouth lesions of erythema multiforme are bullae When they rupture they leave an eroded surface ith ragged remnants of pellicle A show the top of ruptured bulla on the under side of the upper lip B show an erosion simulating a mucous patch at the angle of the mouth, a sit of predilection for mucous patches. For differential diagnosis see Fig 380.

are most apt t appear (Fig 378) For differential points involving the lesions on the mucous membranes see Fig 380. Lesions upon the genitals are rare but they do occur

Malignant Pemphigus and Early Syphilis of the Mucous Membrane.—The type of pemphigus which is associated with the early appearance of bullous lesions on the mucous membranes, subsequent appearance of bullae on the skin, and ultimately fatal outcome has seemed to be more common during the past several years, and the possibility of its confusion with syphilis,

Fig. 578.—Several types of lesions of erythema multiforme on the hands to assist in identifying lesions on the mucous membranes. The cutaneous lesions vary from pink macules to hemorrhagic bullae and are not invariably present. Those shown are the iris type.

therefore, deserves consideration. Malignant pemphigus is of unknown cause. It may attack persons of any age from youth to senility. The prodromal period of mouth lesions unaccompanied by any lesions on the skin may last for several years, with an increasing degree of severity until finally bullae begin to appear about the genitalia and then upon the skin, with comparatively

rapid and fatal progress of the disease with extensive denudation and infection of the entire skin, condylomatous hypertrophy of the bases of the ruptured bullae in the flexures and apposed or

Fig 579 —Erythema multiforme resembling an extensive circinate syphilid.

Fig 580.

MUCOUS LESIONS OF ERYTHEMA MULTIFORME	MUCOUS LESIONS OF EARLY SYPHILIS
Mouth more involved than throat.	Throat apt to be more in olved than mouth.
Process acut	Process more chronic.
Essential lesion ruptured bulla.	Essentiul lesion an eroded papule.
Pellicle tough, mucous membrane-like, shreddy yellowish	Pellicle thin, grayish or pearly easily iped off.
Confluence of lesions common.	Lesions tend to be discrete.
N papules on dorsum of tongue.	Look for papules on dorsum of tongue
Lips and mucosæ livid.	Lips nd mucosæ normal color
Mouth very sore	Mouth not very sore.
Marked fetor may be extreme	*Little or no fetor*
Genital lesions rare	Genit l lesions common.
Previous severe ttacks usual	Previous severe ttack not usual
Bullous lesions, wheals, iri lesions elsewhere (may not be present) Look t backs of hands.	Indolent lesion of syphilis (no bullæ in halt) usually present. Look for palmar papules

ternal surfaces. The differential points in lesions of the mucosae and genitalia are shown in Fig 584.

Aphthae (Mouth and Genital) and Early Syphilis of the Mucous M embranes.—The aphthous lesion may be, but is not necessarily manifestation of herpes, and is often an accompaniment of infections, evidence of hich can usually be found on examination. Aphthous ulcers may

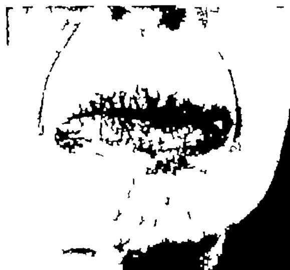

Fig. 381.—A severe grade of mucous erosion usually taken for trench mouth, or in its early stages suspected of being syphilitic, but, in reality due to pemphigus of the malignant type (see Fig. 384).

be accompaniments of intestinal allergies. The characteristic morphological earmarks of herpes the tense, itching, burning, deep vesicles, often grouped, must be borne in mind. In the mouth

Fig. 382.—Condylomas and mucous erosions produced by malignant (vegetative) pemphigus. These lesions and those in the mouth may appear before the bullae on the skin.

the lesions are usually single and the early rupture leads to the formation of small ulcer which is usually very painful. The differential points are shown in Fig. 384 (see also Fig. 387).

Periadenitis Mucosa Necrotica Recurrens and Mucosal Syphilis.—This relatively uncommon condition responds promptly to arsenicals and thus may give the impression of syph-

Fig 583 —Circinat and arciform bullous lesions of pemphigus. For practical purposes ther is no bullous syphilid in dults.

Fig 584.

MALIGNANT PEMPHIGUS	MUCOUS LESIONS OF SYPHILIS
Essential lesion flaccid bulla. (Repeated observation of mouth and throat ma be needed to find one before rupture) Rupture of the lesion lea es an erosion hich heals ith difficulty	Essential lesion papule or erosion. Never bullous in dults.
Look for bullæ in larynx, especially if hoarseness is present.	No bullæ Simply edema and t times slight ulceration.
Pellicle fragile but may sometimes be found just after rupture er erosion	Pearly exudat rather than shred of membrane
Confluent geographic areas, especially over soft palat and uvula.	Little tendency t confluence.
Lesions often appear first about the gums.	Lesion rare on gums.
Mouth very sore	Soreness not extreme
Fetor pronounced	Fetor usually slight.
Surface of tongue usually free until lat	Papules early on tongue surface
Bullæ lat on skin.	N bullæ but other syphilitic lesion
If condylomas present identify bullæ and superficial erosions.	If condylomas present, look for papular or maculopapular syphilid.
Darkfield negative for *Spirochæta pallida*.	*Spirochæta pallida* may be found (caution)

lid, as in 2 out of 3 cases seen by one of us (J H. S.) The larger lesions in the dorsum of the tongue may give the impression of gumma of the tongue but the lesions in the lip or side of the tongue are more suggestive of indolent aphthae. The first case in this experience responded

a therapeutic test for syphilis and was regarded as such for several years, until a second case was encountered in which the nonsyphilitic character of the lesion was undoubted. The first case responded with rapid healing to 3 injections of arsphenamine on several occasions,

Fig. 385

APHTHAE (MOUTH)	LUES II MUCOUS MEMBRANE
Elementary lesion deep vesicle which ruptures and ulcerates.	Elementary lesion papule which erodes.
Ulcer yellow necrotic, excavated.	Erosion flat or slightly depressed, with pearly pellicle.
Ulcer usually 1 to 3 mm. in diameter	Erosion 5 to 10 mm. in diameter
Marked inflammatory areola.	Little reaction about lesion usually
Painful.	Little or no pain.
If any grouping, usually herpetic.	If any grouping, usually arciform.

APHTHAE (GENITAL)	LUES II GENITAL
Definite ulcer depressed border (vesicular stage rarely seen)	Eroded papule.
Angular irregular or stellate.	Margin usually rounded
Necrotic or yellowish base.	Flat or elevated, faint pearly pellicle.
No condylomatous hypertrophy	Condylomas common.
Painful.	Relatively painless.
Darkfield, no *Spirochaeta pallida*.	Darkfield, abundant *Spirochaeta pallida*.

although the involution without the drug was very slow The condition is of unknown etiology The elementary lesion is a nodule beneath the mucosa which enlarges, becomes tender and finally separates a sequestrum following which the lesion heals (Fig. 391)

Fig. 386 —Erosions resembling mucous syphilids, developing on penis and scrotum in a patient susceptible to phenolphthalein.

Marginal and Exfoliative Glossitis (Benign Plaques) and Mucosal Syphilis.—Fortunately even a limited experience enables the beginner to distinguish the more marked examples of marginal glossitis from syphilids of the tongue. The solitary benign plaque, however occurring on the dorsum, is sometimes mistaken for syphilitic leukoplakia or for a mucous patch, from which

Fig. 387 — Aphthous" ulcer on the labium, associated with arthritis and mouth lesions. A similar type of lesion may develop in the condition known as ulcus acutum vulvae. A portion of the labium had been excised for a previous attack. Aphthous lesions may also rarely occur on the scrotum and be confused with mucous erosions. For differential diagnosis see Fig. 388.

Fig. 388.

PERIADENITIS MUCOSA	LUES II MUCOUS MEMBRANES
Elementary lesion deep hard nodule.	Elementary lesion flatter, more superficial papule.
As usually seen, deep ragged excavation, *sometimes with yellow slough.*	Usually level or a shallow flat depression, *with a grayish pellicle.*
Active inflammatory areola.	N inflammatory areola.
Lesions seldom more than one or two at time.	Lesions may be numerous.
Very painful.	Relatively painless.
Darkfield, no *Spirochaeta pallida.*	Darkfield, *Spirochaeta pallida* may be present.

Fig. 389

MARGINAL AND EXFOLIATIVE GLOSSITIS	LUES II MUCOUS MEMBRANES
Confined t tongue margin and dorsum.	Lesions t commissures and on lips, palate, faucial pillars, and tonsils as well.
Plaques if present tend t be anterior t middle of tongue.	Plaques tend to be posterior near circumvallate papillae
Annular or gyrate lively reddish patches with grayish margins, and flat gray plaques on dorsum.	Red papules on dorsum, gray erosion on margin.
Geographic and concentric contours.	N geographic contours.
Dry no erosion or exudate.	Erosion and exudate on marginal lesions especiall
No induration.	Indurated papules on dorsum.
	Concomitant signs of syphilis

later it is really distinguished if it is found that what appears to be gray pellicle is, in reality not removable.

Lichen Planus (Buccal) and Mucous Lesions of Syphilis.—Lichen planus continues its imitation of the eruptive manifestations of syphilis on to the mucous surfaces, and pads the unofficial lists of "leukoplakia" by the inclusion of lesions for which the term is essentially a misnomer. The differentiation is shown in Fig. 390.

Fig. 390.

LICHEN PLANUS (BUCCAL)	LUES II (BUCCAL)
Stellate and punctate mosaic network.	Scattered or isolated, rounded plaques or papules.
Lesions minute (0.5 to 2 mm.).	Lesions larger (4 to 10 mm.).
Silvery color	Flesh color (except leukoplakia).
No erosion. Lesion can be wiped dry without change.	Erosion the rule. Wiping the lesion removes exudate.
Lesions rare on fauces and gums.	Lesions common on fauces, occasional on gums.
No symptoms whatever	Some soreness from erosions.
Lichen planus lesions elsewhere usually present.	Syphilids elsewhere on body

Tuberculous and Syphilitic Fissures and Erosions.—Tuberculosis of the mucosae and syphilis may be distinguished with great difficulty at times on morphological grounds. Therapeutic tests should be made with a soluble mercurial salt to avoid nonspecific temporary arsphenamine effects. The presence of miliary tubercles in the inflammatory periphery of a tuberculous lesion

Fig. 391.—Severe "aphthous" type of ulcer on the tongue. This condition is periadenitis mucosa necrotica recurrens" (see Fig. 388), which may also respond to arsphenamine treatment.

if discoverable is a helpful point. At times the diagnosis can with difficulty be made even after complete study including tissue sections (see Figs. 384, 537, 535)

Heavy Metal Stomatitis and Early Mucosal Syphilis.—This differentiation is obviously of importance, and may lead to the gross mismanagement of patients under treatment, either in the form of overmercurialization under the impression that the syphilis is resistant, or of undertreatment in the supposition that the patient is hypersusceptible. Under careful mouth prophylaxis the incidence of stomatitis is so much reduced as to do away with most of the possibility of error

Fig. 392.—A condyloma of lichen planus on the foreskin. Hypertrophic lichen planus is rare on the genitalia. The usual type is the flat papule on the glans.

Fig. 393.—Another form of lichen planus of the penis. This patient had an active gonorrhea. The sheen is due to reflection of light from the surface of the papules. They have no scale.

Fig. 394.—The penile wart. The term may cover any lesion from true verruca vulgaris, as in this case, to condyloma and chancre. All such lesions should be subjected to darkfield examination. These are small papillomas, discret and hard of surface without pellicle or exudate. Their probable source is from the true warts on the hand by autoinoculation.

and careful mouth prophylaxis incidentally contributes t the control of infectious lesions through cleanliness (Fig. 396).

Ulcus Acutum Vulvæ and Lues II of the Female Genitalia.—This disease, due to the *Bacillus crassus*, affects young virgins especially and is an acutely painful form of ulceration and erosion of the mucous surfaces of the vulva, described in the literature by Lipschutz, Olson, McDonagh,

Fig. 395.

TUBERCULOUS FISSURE AND EROSION	SYPHILITIC FISSURE AND EROSIONS
Erosion or fissure usually redder more inflammatory	Erosion or fissure indolent, even non-inflammatory
Satellite glistening minute miliary papules (tubercles) around border of erosion or ulcer if lesion is on flat mucosal surface	No miliary satellites.
Tends to be painful.	Not so painful
No other definitely syphilitic mucosal lesions.	Associated papules on tongue or mucous patches
Tubercle bacilli in smear	*Spirochete pallida* in darkfield.
Tubercle bacilli in sputum	Sputum repeatedly negative
Signs of tuberculosis in chest or larynx (may be syphilis).	Signs of syphilis elsewhere on body or in larynx.
Tubercles and bacilli in tissue (don't trust mere presence of giant-cells)	Chronic inflammatory and granulomatous picture without tubercles.
Mercurial therapeutic test negative	Mercurial therapeutic test positive (soluble salt)

and Flemerud. The lesions in general conform to the description of aphthae (see differential diagnosis, Fig. 388) Vincent's angina of the vulva must also be borne in mind.

Herpes Progenitalis and Genital Lues II.—It has been held that patients with syphilis are especially prone to relapsing herpes of the genital region, so that this differentiation is occasionally

Fig. 396.

MERCURIAL STOMATITIS	LUES II, BUCCAL
Edema of tongue with dental incisures in margin.	Little local edema, especially of tongue.
Erosion and ulceration, especially of apposed surfaces and crypts.	
Exudate grayish-yellow abundant.	Exudate pearly scant.
Color livid	Color paler red.
Much necrosis and detritus.	Little necrosis or detritus.
Fetor marked.	Fetor slight or none.
Edema, lividity and bleeding of gums, with separation from teeth.	May be patches on gums, but gum tissue firm, pale, not hemorrhagic, not separating from teeth.
No papular lesions (unless those of syphilis)	Papular lesions often found (tongue, dorsum)
Soreness on clenching teeth.	No soreness on clenching teeth.
Marked local adenopathy	Adenopathy general; no local.

BISMUTH STOMATITIS	LUES II, BUCCAL
Marked fetor	No fetor
Black line in gum margin.	No black line.
Pigment patches on mucosa.	No pigmentation.
Other signs as with mercurial stomatitis.	Other signs as with syphilis.

important but seldom difficult, especially if seen early. It should be borne in mind that true herpetic lesions in early syphilis may be infectious and transmit syphilis (Fig. 397).

Lichen Planus and Genital Lues II.—Lichen planus may furnish imitations of syphilids upon the genitalia, especially of the annular type, which, while not strictly mucous lesions, are more deceptive than those in the mouth. It is essential for the practitioner in making differentiation

to learn the appearance of the angular flat, shiny papule of lichen planus (see Fig. 298) The annular lesion of lues II may present shiny surface.

Scabies and Genital Lues II.—The localization of scabies to the genitalia usually occurs in *males, and lesions of both scabies and syphilis may be present It is important to realize, first,* that scabetic burrow or papule may be chancre if sexual intercourse has occurred since the development of the scabetic lesion. One of us (J H. S.) has seen 6 scabetic burrows on the shaft

Fig 297

HERPES PROGENITALIS	LUES II, GENITAL
Essential lesion vesicle	Essential lesion a papule.
Grouped closely usually one or tw groups.	Not grouped, and may be widely scattered or arciform.
Confluent with polycyclic border	Discrete.
Inflammatory areola.	Indolent, not markedly inflammatory
Inclined to crust if exposed.	Dry if exposed.
Yellow necrotic base if ulceration and infection occur	Grayish exudative pellicle if moist.
Characteristic itching or burning prodrome.	N symptoms, or slight soreness after lesion develops.

of the penis, from five of which *Spirochaeta pallida* was obtained on scraping, the infection being traced to intercourse with chambermaid just before her secondary eruption appeared and she came under treatment. The sign manual of the individual scabetic lesion is, of course, the burrow which on the genitalia forms a wavy or irregular elongated papular elevation as contrasted with the round papule of syphilitic lesion. It must be remembered that papulo-erosive syphilids may

Fig. 298.

LICHEN PLANUS GENITAL	LUES II GENITAL
Elementary lesion quadrangular or polygonal papule.	Elementary lesion an oval or round papule.
Papule is small (0.5 t 2 mm.)	Papule is larger (2 to 10 mm.)
Annular lesions are segmented into miliary papules.	Annular lesions usually continuous ring
No erosion occurs even on moist surfaces.	Mucous erosion frequent.
Lesions may be flesh colored, but are often whitish or gray	Lesions usually flesh colored.
N induration	Fleshy induration not uncommon.
Other lesions of lichen planus in skin and mouth	Other lesions of syphilis

develop upon scabetic papules in the patient who has both diseases. The identification of the scabetic infection by the localization of typical lesions to finger webs, forearms, axillae, nipples (women) waist line, and anogenital region, ith nocturnal itching prominent symptom, is essential.

THE CONSTITUTIONAL ASPECTS OF EARLY SYSTEMIC SYPHILIS

Symptoms of Generalization.—The generalization of a syphilitic infection is accompanied in a certain proportion of cases by systemic symptoms and constitutional manifestations which may range from slight malaise to the gravest prostration and cachexia. In general, the symptoms are surprisingly mild, considering the extent of systemic involvement shown by pathologic and experimental study They may begin as early as a week after the appearance of the chancre. The proportion of cases in which there arise constitutional symptoms sufficiently marked to attract the patient s attention certainly does not exceed 50 per cent (47 1 per cent in our series) Fournier estimated that

50 per cent of women and 75 per cent of men experience no significant constitutional symptoms from their infection.

Our own experience accords with his. Sixty-three per cent of women and 48 per cent of men in our series had constitutional symptoms from their infection. No reason can be assigned for the preponderance of women. It is notable that they as a sex are in similar proportion more reactive to intensive (five-day etc.) treatment for syphilis. The general health in either sex may remain unaffected at times even in conjunction with the most malignant eruptive phenomena and severe grades of internal change, and patients have even told us they had not known what good health was until they developed an early syphilid.

The constitutional symptomatology of early syphilis does not in general have a high diagnostic value. Here and there a distinctive symptom stands out, but in general corroborative evidence must be sought from a thorough general examination and the serologic tests before a diagnosis can be made. An account of the symptomatology of early syphilis will, however, assist in arousing suspicion and lead to fuller investigations of special cases in which constitutional symptoms may be the only expression of the infection, or in which confusion with other diseases is possible.

Fig 300

SYMPTOMATOLOGY OF EARLY CONSTITUTIONAL SYPHILIS

	Per cent.		Per cent.
Sore throat	53	Iritis	3
Malaise	42	Vaginal discharge	3
Headache	24	Anemia	2
Loss of weight	18	Deafness	2
Fever	14	Hoarseness	2
Meningismus	8	Myositis and myalgia.	2
Gastro-intestinal symptoms	7	Nocturnal ostealgia	2
Rheumatism	7	Periostitis	1
"Neurotic" symptoms	5	Arthritis	1
Bone complaints	5	N VII palsy	1
Pseudotuberculous symptoms	5	Insomnia (essential)	1
Nervousness	4		

The conspicuous place occupied by the *syphilitic angina* is at once apparent, and the importance of more than a local examination of patients who complain of sore throat may be inferred. The stripped examination and routine serologic test (Thomas and Goldstein 1941) would save many blunders (see Figs. 348 373). *Headache*, if persistent, is an important symptom of secondary syphilis. If the occipital head pain of meningismus be included in this group, the proportion rises to 31 per cent. Nearly a third of all syphilitics who have any constitutional symptoms whatever to bring them to a physician, therefore, complain of headache. The combination of persistent headache and sore throat in any practice would yield a harvest of early syphilis if adequately investigated or given a routine serologic test and an inspection of the skin. On the other hand the anginal symptoms of infectious mononucleosis must be kept in mind, and heterophile antibody test and differential blood count invoked. Sadusk (1941) found 7 per cent of infectious mononucleosis presenting a macular eruption. Absence of hand and foot lesions and large cervical adenopathy speak against syphilis. *Fever* of a mild grade, seldom exceeding 100° F afternoon temperature is a fairly common accompaniment of the constitutional manifestations. Several types are described with great minute-

ness by Fournier but those for which the general clinician should be most on the alert are the irregular slight afternoon rise suggesting tuberculosis or endocarditis and the intermittent fever associated with a "typhoid" state of prostration and cachexia with a sparse roseola. This "syphilitic typhoid," while rare, is at times exceedingly puzzling.

Pseudotuberculous Symptoms.—The combinations of slight fever loss of weight, night-sweats, gastro-intestinal symptoms, asthenia, nervous irritability and cough which early syphilis may present are important from the standpoint of differential diagnosis for tuberculosis. The impossibility of diagnosing syphilitic pneumonitis by any intrinsic sign makes it difficult to decide just how often errors actually arise from the confusion of these two diseases in their early stages. Cough is an unusual symptom in early syphilis, but pseudotuberculous pictures made up from the other elements in the table are so far from unusual as to justify a serologic test on all cases of suspected early tuberculosis. Again the biologic false positive in atypical upper respiratory infections (virus pneumonia?) must be recalled. Arthritic pains with anemia and loss of weight, another group of symptoms by no means rare in both diseases, demands careful scrutiny The combination is one of the chief causes of error in the misdiagnosis of tuberculids as syphilis. The well-recognized possibility that a syphilitic infection superimposed on a latent tuberculosis may cause a flare-up of the latter must always be borne in mind.

Headache and Head Pain.—Fournier with characteristic detail distinguishes three types of head pain which can be identified in early syphilis. The commonest is a *diffuse cephalalgia*, possibly the expression of a low-grade encephalitis but of unknown etiologic mechanism Second, in our experience is *meningismus or occipital headache* with occasional stiffness of the neck, associated with cases of basilar meningitis. The least common type is the localized area of osteitis giving rise to *spotlike pains* in the head exactly localizable by pressure on the affected areas. The tendency to a nocturnal character of syphilitic headache, while recognized, is often exaggerated in diagnosis, and should not lead to neglect of proper investigation of persistent headache of any type.

Gastro-intestinal Symptoms.—In early syphilis these may range from anorexia to the nausea and projectile vomiting associated with intracranial pressure in high grades of early cerebral and meningeal involvements. Nausea, vertigo and vomiting, with deafness and tinnitus, is an expression of changes in the eighth nerve, the vertigo nausea and vomiting expressing the vestibular part of the complex. The symptoms of the not uncommon syphilitic catarrhal gastritis of the early stage are not highly specific, although Eusterman has called attention to the frequency of subacidity (see Chapter XVII) Reynolds (1942) has described an interstitial inflammation in secondary syphilis with stenosing possibilities. Fournier describes syphilitic bulimia and a pseudo-hysterical anorexia.

"Rheumatism"—The catch basket of "rheumatism" expressing the osseous arthritic and myalgic symptoms of early syphilis, is responsible for frequent errors in diagnosis. The systematic use of a reasonably sensitive serologic test under proper control in all aspects of bone, joint, and muscle involvement in patients between the ages of fifteen and thirty would, without question reap a considerable harvest of early syphilis. Many of these "rheumatic" symptoms have the vagueness expressed in the lay term "grippy" That they may constitute the prodromes or early manifestations of the gen

eralization of the infection makes their recognition especially important. Traditionally the leading symptomatic feature of the bone changes of early and recurrent syphilis is pain nocturnal in character exaggerated by heat and relieved by movement of the affected part. Overemphasis of these peculiarities would lead to the overlooking of a number of cases since in not more than half the patients with osseous changes under our observation has this syndrome appeared. Wile and Senear (1916) found 56 per cent of their early cases to present actual clinical bone lesions.

Osseous System.—The bone lesions of syphilis are fully described in Chapter XVI, and the following résumé simply completes the symptomatic picture of secondary syphilis.

Periostitis.—This involves especially the long bones, the tibia being, by all means, the most frequent. Early syphilitic periostitis, clinically is sharply localized process, seldom covering more than few square centimeters and presenting as somewhat doughy elevation of the bone, noninflammatory without any sign of fluctuation. On the tibia the lesions develop most often on the anterior face and edge. Its most distinctive feature is the highly localized point of exquisite tenderness which can be found by searching the entire surface of the tumefaction with the finger tip. The tenderness on pressure at this one point, in contrast to the insensitiveness of the remainder of the lesion, may be so exquisite as to result in shriek of protest from the patient. Slighter

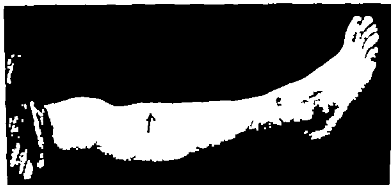

Fig. 400.—A typical localization for syphilitic secondary periostitis. The roentgen-ray examination is negative.

degrees of periosteal involvement in bones covered by muscles, when not marked enough to produce tumefaction, may be detected by gripping or wringing the extremity as described in the technic of examination. Periosteal changes over the sternum, the clavicles and scapulae, and the ribs are seldom observed, probably because not looked for. Periosteal changes may lead to actual productive growth of bone, forming definite thickenings and exostoses which can be detected clinically.

Ostealgia is the term applied to the indefinitely localized bone pains of secondary syphilis for which no pathologic background can be found. A fair proportion of the diffuse headache of the secondary period, and sternalgia and pleurodynia, as Fournier points out, belong under this category and are especially common in women.

Osteomyelitis.—Wile and Welton (1941) report this in early syphilis, and Plan and Frazier (1941) report 2 cases following blood transfusion (same donor). Reynolds and Wasserman (1948) review the literature of destructive lesions and believe them not uncommon. Pathologic fracture also occurs.

Arthritides.—These are relatively uncommon in secondary syphilis (only 1 per cent in our series). Part of this rarity is due to lack of complete investigation, especially in women. Low or insignificant grades of inflammatory reaction, an unusual retention of mobility, pain without any evidence of actual lesion, and exaggeration on rest and relief by movement are the conspicuous points. Hydrarthrosis is not common, according to Fournier. True polyarthritis in early syphilis is known to occur but is very rare and, t judge by reported cases, presents little that is really characteristic.

Tenosynovitis, Bursitis.—These features of early syphilitic involvement of the skeletal system are rare, and in our experience have presented no distinctive features from which diagnosis could be made without resort to collateral evidence.

Myopathies.—Myalgia is a common complaint among the nondescript general symptoms of early syphilis, and presents no distinctive features. It may be associated with varying degrees of muscular weakness, or with actual amyotrophic changes, on the authority of Fournier although this complication must be very rare. One of the bizarre and rare myopathies of secondary syphilis is contracture of the biceps. There is no visible or palpable pathologic change beyond the fixation of the arm in a semiflexed position. Myositis in secondary syphilis may be recognized by the usual signs of localized tenderness of the muscle tumefaction, pain on movement, etc.

Lymphatic System.—Involvement of the lymphatic system in secondary syphilis is one of the most characteristic aspects of this stage of the disease. Seventy per cent of cases in our experience present this feature (Tomé y Bona, 1936 85 per cent) Clinically three groups of lymph nodes in addition to the inguinal are most often concerned in the adenopathy—the suboccipital, the cervical (especially the posterior cervical) and postauricular and the epitrochlear Axillary inframammary submental, and submaxillary groups are usually unaffected. The nodes are discrete usually painless may be sufficiently enlarged to be easily visible and never break down. We have not known the uncomplicated general adenitis of syphilis to reach the proportions of the marked adenitis of early Hodgkin s disease or lymphatic leukemia in white patients, but Moore (personal communication) states this may occur in Negroes (Fig 348) The grade of lymphatic involvement has little relation to the severity of the affection, and may be marked or absent in cases exhibiting a distinctly malignant tendency General adenitis may be one of the earliest signs of the generalization of the infection, and is at times the first thing in a general scrutiny of the patient which suggests syphilis and leads to a painstaking search for confirmatory evidence. The epitrochlear enlargement, when marked and symmetric, has high suggestive value. Beeson (1935) found 27 per cent, in early syphilis

Lymphangitis in secondary syphilis is, in my experience an excessively rare complication It is indolent, cordlike, noninflammatory usually affect the long lymphatic chains such as the brachial, and may be confused on superficial examination with phlebitis. It may develop on the dorsum of the penis, as already mentioned, t the time of or just before the appearance of the secondary eruption.

Visceral Syphilis in the Secondary Period.—Syphilis of the gastro-intestinal tract and of the liver and spleen are fully discussed in a special chapter so that their existence merely requires mention here.

The Liver—Syphilitic hepatitis of varying grades of severity is an occasional feature of the florid stage of syphilis, and is more fully discussed in Chapter XVIII. I the form of *icterus gravis* it may be a precocious manifestation, assuming an alarming form before the secondary eruption is fully developed. The milder grades of involvement are associated with slight painless enlargement of the liver mild icteric tinge t the sclerae, with slight discoloration of the skin, and bile in the urine The mild type presents no distinctive peculiarities. I modern practice it is essential t distinguish it from the icterus produced by the administration of arsphenamine, and from intercurrent catarrhal and infectious jaundice (see p 873) differentiation rendered difficult at times by the fact that the therapeutic shock of the first arsphenamine injection may cause slight flare-up of a subthreshold syphilitic process in the liver

Splenic Enlargement.—Splenic enlargement as show by Wile and Elliott can be recognized by palpation in about 26 per cent of patients during the florid secondary stage This proportion drops to about 5 per cent in latent and late syphilis. As contributory evidence in the bsence of more obvious signs, this splenomegaly has value, though it fails to distinguish acute syphilis

from such infections as typhoid and malaria, which it may simulate. On the other hand, suspected early tuberculosis which presents splenic enlargement deserves painstaking search for evidence of early syphilis. The palpable spleen should always be looked for in the routine examination, and it times arouses important trains of suspicion in examining patients with bone lesions, "neurasthenia," etc.

The Kidney.—Renal irritation of the type usually associated with febrile constitutional conditions and acute infections may form part of the clinical picture of early syphilis in small proportion of cases. Small amounts of albumin, occasional casts, and red blood cells appeared in 7 of 80 cases studied by Kolmer and Klauder. These authors believe such changes to be due to actual spirochetal invasion of the kidney. There were no changes in renal function.

Acute Syphilitic Nephritis.—The distinctive nephropathy of early syphilis is the so-called acute syphilitic nephritis, distinctly rare complication, beginning frequently before the appearance of the eruption. The average onset is about the fifth month of the infection. It may, however, be delayed. A late appearance is, however, strongly against an unqualified diagnosis of acute

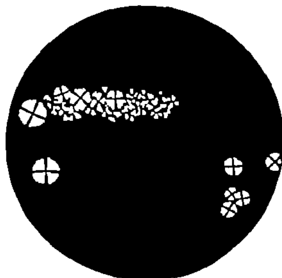

Fig. 401.—Double refracting lipoid globules, as seen by polarized light, from the urine of patient with acute syphilitic nephritis, or rather parenchymatous nephritis in the course of syphilitic infection. The upper group of globules are contained in the body of lipoid or waxy cast.

syphilitic nephritis, since chronic or subacute parenchymatous nephritis and nephroses in syphilis are not *ipso facto* of syphilitic origin and may show no response to treatment.

Abrupt onset early in the course of the infection, marked edema even to anasarca, progressive weakness with anemia, and surprisingly little effect on the general health in other ways, mark the clinical picture with minor variations. The urine exhibits characteristically tremendous albuminuria, which is almost distinctive in itself. It has repeatedly been observed to boil solid, and 83 Gm. per liter have been reported. Casts may be present in the numbers found in cases of puerperal eclampsia; epithelial débris, but little or no blood is present. Much emphasis has been placed on the presence of double-refracting lipoids in the urine (Fig. 401). Their detection requires polarizing microscope (Nicol prisms) which is seldom available. Stokes has had occasion to realize that the finding of these lipoids is only of qualified diagnostic value. *Spirochaeta pallida* has been reported in the urine by Hoffman and by Dreyer and Toepel, but under conditions which make it doubtful if the findings were authentic, or at least of renal origin. The risk of uremic complications is not considerable although Elliott and Todd have shown that an increase in blood urea occurs. Blood pressure is little affected. In differential diagnosis the clinical features of secondary syphilis may be completely masked. The Wassermann reaction has the qualified value already suggested. Absence of other causes for nephritis may arouse suspicion. The therapeutic test is without question the most important single means of identifying syphilitic nephritis. It should be performed with arsphenamine, since mercury is much less satisfactory. The latter

drug may give rise to prolongation of the renal symptoms, instead of recovery and may as in Stokes case, be powerless to prevent the onset of the complication in the first place.

The differentiation of acute syphilitic nephritis from renal irritation produced by intensive treatment with arsphenamine and mercury can be made, as rule, by the urine. The signs of renal irritation from treatment appear in the following order as the irritation progresses (1) Polyuria, (2) low specific gravity (3) casts (4) albumin (small amount) and (5) red blood cells. Those of syphilitic nephritis are in order of importance: (1) Albuminuria (marked) (2) oliguria (3) high specific gravity (4) casts (5) red blood cells. The differentiation of acute syphilitic nephritis from treatment nephrosis (high albuminuria), which incidentally seldom develops so early in the disease, is made by the absence of casts and red blood cells, and of constitutional symptoms and impaired renal function in the nephrosis. The ease of applicability and the safety of a small dosage arsphenamine therapeuti test (1 to 3 dg) which has little or no effect on the ordinary nephritis, should lead t considerable increase in the number of cases diagnosed in the future. The literature of this aspect of early syphilis is reviewed by Stokes, Cole, Elliott and Todd, Patton and Corlette.

Early Syphilis of the Eye—Neuroretinitis.—Eye complications appeared in 2.8 per cent of 3244 patients with early syphilis in the Cooperative Clinical Group series reported in 1932 Colored patients have eye involvement more than three times as frequently as white patients, and women oftener than men of both races. Involvement of the optic nerve and retina in early syphilis, while frequent, is probably not so common as some of the earlier studies made in connection with changes in the nervous system suggest. Routine examination of the fundus is necessary to detect many involvements of which the patients make no complaint, and which may rapidly disappear under treatment.

In Wile and Stokes study slight degrees of neuroretinitis were reported in 15 of 27 untreated cases routinely examined, proportion which in view of later experience is probably too high Of 62 patients with secondary syphilis who had fundus examinations, 13 per cent had definite neuroretinitis In early syphilis, the Cooperative Clinical Group found that neuroretinitis was 11 1 per cent of all eye complications. Only 2 patients in McFarland and Stokes' later series of 231 early infections, who were not the victims of neurorecurrence, presented grades of optic neuritis sufficiently marked to attract clinical attention. One of these was high-grade inflammatory process in one eye which had scarcely been noticed by the patient. In our experience involvement of the second nerve is more conspicuous and serious as manifestation of relapse in inadequately treated infections. Slight veiling of the disc should be interpreted by an experienced observer before it is reported as neuroretinitis.

Woods excellent monograph (1943) lists eye lesions in secondary syphilis in 4.5 per cent of cases and 9 8 per cent in recurrent syphilis. These include not uncommon conjunctivitis, very rare interstitial keratitis (0.3 per cent) iritis (4 per cent) the commonest lesion, plastic or nodular in type. Relapsing iritis is common with neurorecurrence. Ciliary syphiloma is now rare. Chorioretinitis is late secondary lesion probably uncommon. Chorioretinitis juxtapapillaris is an exudative lesion, and uritis papulosa stands midway between chorioretinitis and syphilitic optic neuritis. Optic nerve hyperemia often accompanies abnormal spinal fluids. Optic neuritis may be visible or retrobulbar Ch ked disc may have surprisingly little accompanying visual failure.

Disorders of the extra-ocular nerves (III, IV VI) are considered under neurosyphilitic lesions.

Iritis is usually a late secondary lesion seldom appearing before the sixth month of the infection and often as late as the second year Thirty to 40 per cent of iritis is syphilitic and iritis constitutes 73 3 per cent of the total eye complications of early syphilis. It seems to be more frequently an accompaniment of the more severe infections. The incidence in our series did not exceed 3 per cent in the general run of cases. The tardiness of the manifestation and lack of specific earmarks may lead to failure to recognize the syphilitic origin unless a routine Wassermann test is employed

According to Benedict, syphilitic iritis is plastic and passive in character cellular and serofibrinous exudate appearing between the iris and the lens ith the formation of adhesions (synechia), often total or annular in character in which latter case the iris may balloon, forming the so-called "iris bombée Pain and circumcorneal injection during the acute phase are pronounced. Papillary iritis with minute reddish papular elevations along the inner margin of the iris is quite distinctively syphilitic, and should not be confused with tuberculosis. The practitioner should always scrutinize sluggish, irregular or apparently fixed pupil in young patient with great care, and not be too ready to suspect neurosyphilis instead of old iritis with adhesions. Atropine will, of course, differentiate the two by causing dilatation of the free pupil, and demonstration of the adhesions of posterior synechia.

In severe grades of papular cutaneous secondaries, papules may appear upon the conjunctiva and at the inner canthus of the eye, and may even become pustular or ulcerate. Their accompaniments serve to identify them without difficulty J. H. S. has seen only three examples.

Interstitial keratitis and dacryocystitis may occur with the secondary outbreak, but are extremely rare complications. Interstitial keratitis and kerato-iritis occurred in 0.3 per cent of 3844 patients with early syphilis (Coop. Clin. Group) Parker (1930) gives details of 8 cases.

The Ear.—Involvement of the ear in the acute stage of syphilis includes syphilitic auditory neuritis, and acute syphilitic labyrinthitis, both of which are fortunately unusual complications, or at least rarely severe enough to attract clinical attention except in mistreated cases. They should be looked upon as manifestations of syphilis of the nervous system The Herxheimer reaction following a first injection of arsphenamine in what appears to be a patient in good condition may result in abrupt total and irremediable deafness. In these patients it is usual after the accident to obtain a history of tinnitus and beginning deafness which were present before the injection was given. Careful attention to partial deafness and the presence of tinnitus in every early infection would identify most cases and should serve as a warning to prepare the patient with mercury or bismuth and iodide before using arsphenamine. Acute syphilitic labyrinthitis is rare.

In classical example under Stokes observation, before the Wassermann test came into general use, the vomiting and uncontrollable vertigo were complete puzzle until the remains of fading roseola were identified. Auditory involvement is likely to be coincident as part of the eighth nerve involvement in the meninges and may result in ultimate deafness in spite of treatment. In Wile and Stokes series 5 of 13 cases examined for involvement of the cochlear and vestibular mechanism by reduced bone conduction and hearing tests showed evidence of changes ascribed to the disease. In view however, of subsequent studies by Goeckerman, Barlow and Stokes, we are inclined to rate this proportion also as too high for application in clinical practice The classical discussion of this field is that of Alexander in the Jadassohn Handbuch in 1929. Ciocco and Weinstein have from general study of the eighth nerve in 256 patients with syphilis, concluded that involvement of this nerve is more frequent in neurosyphilis than in other aspects of the disease but that diagnosis of syphilis cannot be based on *impaired eighth nerve function alone.*

For the practitioner the development of deafness or vestibular symptoms in young persons should be the signal for a blood serologic test and examination by an aurist.

Severe rupial lesions may involve the uricle and the canal, and papular lesions on the auricle must be distinguished from those of the papulonecrotic tuberculid of the face, which present characteristic necrotic centers. Pronounced edema of the pharynx in syphilitic angina may produce secondary symptoms of otitis media from closure of the eustachian tubes. There are no distinctive clinical earmarks of syphilitic otitis media as such, though it is said to exist.

W found that reduction of bone conduction with normal hearing, while it occurs frequently in syphilis, likewise occurs so frequently in its absence as to be untrustworthy as diagnostic criterion when taken alone.

drug may give rise t prolongation of the renal symptoms, instead of recovery and may as in Stokes s case, be powerless t prevent the onset of the complication in the first place.

The differentiation of acute syphilitic nephritis from renal irritation produced by intensive treatment with arsphenamine and mercury can be made, as rule, by the urine. The signs of renal irritation from treatment appear in the following order as the irritation progresses: (1) Polyuria (2) low specific gravity (3) casts, (4) albumin (small amount) and (5) red blood cells. Those of syphilitic nephritis are in order of importance: (1) Albuminuria (marked) (2) oliguria; (3) high specific gravity; (4) casts (5) red blood cells. The differentiation of acute syphilitic nephritis from treatment nephrosis (high albuminuria) which incidentally seldom develops so early in the disease, is made by the absence of casts and red blood cells, and of constitutional symptoms and impaired renal function in the nephrosis. The ease of applicability and the safety of small dosage arsphenamine therapeutic test (1 to 3 dg), which has little or no effect on the ordinary nephritis, should lead to considerable increase in the number of cases diagnosed in the future The literature of this aspect of early syphilis is reviewed by Stokes, Cole Elliott and Todd, Patton nd Corlette.

Early Syphilis of the Eye—Neuroretinitis.—Eye complications appeared in 2.8 per cent of 3244 patients with early syphilis in the Cooperative Clinical Group series reported in 1932. Colored patients have eye involvement more than three times as frequently as white patients, and women oftener than men of both races. Involvement of the optic nerve and retina in early syphilis, while frequent, is probably not so common as some of the earlier studies made in connection with changes in the nervous system suggest. Routine examination of the fundus is necessary to detect many involvements of which the patients make no complaint, and which may rapidly disappear under treatment.

In Wile and Stokes study slight degrees of neuroretinitis were reported in 15 of 27 untreated cases routinely examined, proportion which in view of later experience is probably too high Of 92 patients with secondary syphilis who had fundus examinations, 13 per cent had definite neuroretinitis. In early syphilis, the Cooperative Clinical Group found that neuroretinitis was 11 1 per cent of all eye complications. Only 2 patients in McFarland and Stokes later series of 231 early infections, who ere not the victims of neurorecurrence, presented grades of optic neuritis sufficiently marked to attract clinical ttention. One of these was high-grade inflammatory process in one eye which had scarcely been noticed by the patient. In our experience involvement of the second nerve is more conspicuous and serious as a manifestation of relapse in inadequately treated infections. Slight veiling of the disc should be interpreted by an experienced observer before it is reported as neuroretinitis.

Woods excellent monograph (1945) lists eye lesions in secondary syphilis in 4.5 per cent of cases and 9 3 per cent in recurrent syphilis. These include not uncommon conjunctivitis, very rare interstitial keratitis (0.5 per cent), iritis (4 per cent), the commonest lesion, plastic or nodular in type. Relapsing iritis is common with neurorecurrence. Ciliary syphiloma is now rare. Chorioretinitis is late secondary lesion probably uncommon. Chorioretinitis *juxtapapillaris* is an exudative lesion, and *neuritis papulosa* stands midway between *chorioretinitis* and *syphilitic optic neuritis*. Optic nerve hyperemia often accompanies abnormal spinal fluids. Optic neuritis may be visible or retrobulbar Choked disc may have surprisingly little accompanying visual failure.

Disorders of the extra-ocular nerves (III IV VI) are considered under neurosyphilitic lesions.

Iritis is usually a late secondary lesion seldom appearing before the sixth month of the infection and often as late as the second year Thirty to 40 per cent of iritis is syphilitic and iritis constitutes 73 5 per cent of the total eye complications of early syphilis. It seems to be more frequently an accompaniment of the more severe infections. The incidence in our series did not exceed 3 per cent in the general run of cases The tardiness of the manifestation and lack of specific earmarks may lead to failure to recognize the syphilitic origin unless a routine Wassermann test is employed

This state of affairs is natural enough. The lesions of the nervous system usually most readily detected in ordinary examination are the residua of degenerative processes, and hence of consequences rather than of antecedents, of scars rather than active lesions. Early processes, in their preventive period in the nervous system, are apt to be devoid of other than irritative signs and symptoms, and these, even, in keeping with the general rule throughout the disease, are apt to be inconspicuous. When gross signs appear they usually mean serious damage, not infrequently as in neurorecurrences involving certain of the cranial nerves, damage which is irreparable. It is essential therefore, to realize from the start that the detection and treatment of neurosyphilitic involvement early in the disease at a time when the preventive value of its recognition is highest, demands systematic examination of the spinal fluid in every case The Cooperative Clinical Group figures bear out this statement in striking fashion. Whereas only 1 7 per cent of 2269 patients with secondary syphilis had clinical signs, 32.7 per cent of 1747 whose fluids were examined, were abnormal

The relation of symptoms and signs to asymptomatic neurosyphilis detected only by examination of the spinal fluid is further indicated in relation to age of infection in Fig 402

Fig. 402.

PROPORTION OF ABNORMAL FLUIDS TO POSITIVE NEUROLOGIC SIGNS

Author	Cases.	Phase of syphilis	Positive fluids, per cent.	Positive symptoms, per cent.	Positive signs, per cent.
Stokes-McFarland	114	Early secondary untreated.	37	16	
Moore	353	Primary and secondary one year	20 8 to 22 1	30	23
Fordyce-Rosen.	213	Late secondary two years.	76	43	64

While due allowance must be made for the many factors influencing the collection of such data, it may reasonably be inferred that the longer the involvement of the nervous system persists, the larger the proportion of patients who show clinical symptoms and signs. The observations of Fildes *et al.* tend to confirm this conclusion. It is evident, therefore, that the detection of early neurosyphilis should not be allowed to rest on signs and symptoms alone, but should be accomplished primarily by a combination of the spinal fluid examination with clinical study This proviso of a combined study brings into the field of diagnosis those patients with unmistakable lesions of the nervous system, affecting especially the cranial nerves, and those with precocious gummatous or vascular changes, who have negative or nearly negative spinal fluids.

Immunological and Mechanical Background of Early Neurosyphilis.—The existing state of knowledge and opinion on these fundamental considerations can be fairly summarized in the following way: the approach of *Spirochaeta pallida* to the nervous system must be by way of the vascular system. The older notion that mere geographic propinquity so to speak, as in extragenital chancres about the face, increases the likelihood of neurosyphilitic involvement is unsupported. The peculiarities of the vascular supply of the nervous system serve, therefore, in the writings of a number of authors to explain many of the clinical features of neurosyphilis. The organisms conveyed to the nervous system by the blood stream are deposited first in the meninges

from which most of the nervous system derives its blood supply Hence, early neurosyphilis is overwhelmingly meningeal and meningovascular in its signs and symptoms. The richest blood supply in the nervous system is t the base of the brain. Basilar meningitis is therefore the fundamental first sign of invasion of the nervous system by *Spirochaeta pallida*, and cranial nerve palsies, optic nerve involvement, headache and increased cell counts on the fluid may be and are, in fact, the expected first signs and symptoms. Later neurosyphilis assumes a distribution for which Gennerich invokes Kafka hydromechanical theories of the distribution of organisms by way of the spinal fluid. The rhythmic pulsation of the cerebrospinal fluid-containing sac under the action of the arterial pulse, tends, as sand is shaken in sifter t distribute solid particles to the most dependent portions—namely the horizontal-lying meningeal floor of the brain base and the most dependent portion of the cord—the roots of the lumbosacral sensory nerves, the spinal root ganglia. This attractive mechanical explanation must not, of course, be expected to cover all observed phenomena. The crypts and funnels about the dural reflections on to the cranial and spinal nerves may however because of their relative inaccessibility and attenuated vascular supply be conceived of as good lurking grounds for organisms. For the vascular supply of the nervous system not only acts as the distributor of the infecting agent, but provides the chief route for the supply of antibodies and medicaments to control the infection once it has been distributed.

It is to be expected therefore, as clinical experience abundantly shows, that while meningeal syphilis is the earliest and most active manifestation of the disease in the nervous system it will likewise be the most responsive to treatment. It is, therefore a very practical maxim that the time to treat syphilis of the nervous system is while it is near the blood supply to which it owes its initial distribution—i.e while it is meningeal. It follows, too, that if relapse occurs in a meningeal neurosyphilis it will be most likely to localize at those points where the meninges are least accessible to protective and therapeutic agents as in neurorelapse and recurrence, which in the large proportion of cases involve the cranial nerves within the meninges. It is important, however to keep constantly in mind that not all early syphilis of the nervous system will bear the meningeal stamp, and that early diffuse and localized involvement of both parenchyma and vessels presents itself in the absence or relative unimportance of meningeal reaction (negative or slightly abnormal spinal fluid)

The balance between infection mass or quantity of organisms present in the body and the resistance aroused in the subject is in all probability one of the most important aspects of the immunological background of early neurosyphilis. It is quite generally conceded that the nervous system is largely dependent upon antibody protection derived from the defense reactions of other structures in the body In other words, it is poorly equipped to defend itself, for the proportion of reacting tissue to more or less inert parenchyma is small. If the character of the infection in the body is such as to arouse sharp defence, as in the development of marked involvement of skin and bones and large viscera, the nervous system is pt t be protected, even though the initial invasion be severe, by copious production of antibodies On the other hand, if the patient shows little general reaction to his infection, even relatively mild invasion of spirochetes may carry neurosyphilitic process through to disastrous termination. In support of these generalizations the apparent immunity of patients with severe late cutaneous lesions and marked visceral changes from pronounced neurosyphilitic manifestations is generally cited. This explanation paradoxically can be applied to the reported greater incidence of neurosyphilis in patients with papular as contrasted with macular secondaries, for the sharper reaction in the former while it does not prevent the initial wave of involvement of the nervous system early in the disease, provides the needed antibodies t overcome it subsequently during the latent period.

While the exact detail of these considerations is far from being worked out, there is no reasonable doubt that it is highly important to keep constantly before one the necessity for conserving and developing the specific resistance of the patient to *Spirochaeta pallida* throughout the early stages of the disease as a protection to his nervous system and not to give oneself too un

qualifiedly to merely spirillicidal attacks on the organism which at their best may so easily fail to reach some difficultly accessible corner of the most vital of structures. It is at this point exactly that the deficiencies of an intermittent arsenical therapy have become disastrously evident, and the comparatively high incidence of neurorecurrence in patients who have been insufficiently treated with heavy metals has occasioned alarm among conservative syphilologists. On the other hand, massive dose arsenotherapy (five-day drip) has to its credit a remarkably low incidence of spinal fluid abnormality. It is the combination of arsenical and bismuth, however, which apparently yields the best ultimate results.

The influence of strains and other protective factors is considered in Chapters I and X.

Sequence of Spinal Fluid Findings in Early Syphilis.—Once the nervous system has been invaded by way of the meninges at the outset of an infection, the succession of events is to some extent reflected in the spinal fluid findings at various periods during the first two years. The first warning of meningeal involvement and reaction is the rise in cell count (Fig. 403) and globulin content. The former, in our experience, is the more trustworthy sign. The Wassermann reaction lags behind as an index of the later parenchymatous extension of the syphilitic process. At first entirely negative, even in the presence of a marked pleocytosis, the Wassermann reaction becomes positive first on large amounts of fluid and finally when a fully developed neurosyphilis is established, strongly positive even on small amounts. The detection of early involvement of the meninges is particularly dependent on a complete examination of a properly drawn spinal fluid, for a slight increase in cell count cannot be recognized if only a Wassermann reaction is done or a blood-contaminated specimen is obtained through faulty technic. The colloidal tests in early cases are often negative, and it is not until the process is fully developed that one obtains the striking first-zone curve that so often marks the severe neurorecurrence, though without necessarily indicating an ultimate paretic outcome.

It is evident, therefore, that on whatever basis the incidence of positive Wassermann reactions on the fluid, globulin increase, and cell count be calculated, the increase in cell count tends to lead the list as the earliest and most conspicuous sign of meningeal reaction, and that the Wassermann reaction lags behind, not reaching its full proportion of positive results until the infection is well established and, in fact, enters upon the clinical recurrent or latent stage after a duration of from one to two years. It is therefore doubly important to insist on accurate and complete cell count reports on the spinal fluids of early syphilis. Nearly 60 per cent of the abnormal fluids in the Cooperative Group's large series showed only a rise in cell count with or without an increase of protein, the Wassermann and colloidal tests being negative.

Relation between the Abnormal Spinal Fluid and the Positive or Negative Blood Wassermann Reaction in Early Syphilis.—The proportion of patients with early neurosyphilis whose blood Wassermann is negative while the spinal fluid is positive is small in the early years of the disease (5 to 8 per cent). The aid afforded by the blood test in detecting neurorecurrence emphasizes an axiom now generally accepted by all who have to deal with early syphilis, that the fixed or relapsing blood Wassermann reaction should always inspire not only cardiovascular study but also a thorough search for involvement of the nervous system, including a spinal fluid examination. It should never be

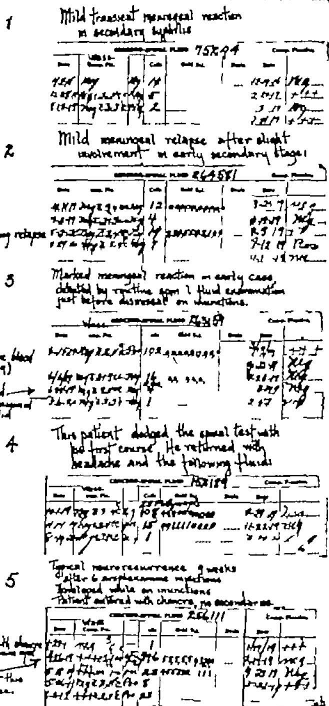

Fig. 403.—Early neurosyphilis. A slight rise in cell count is an important warning of meningeal reaction or impending relapse (see p. 617 Neurorecurrence). It should always be closely watched and treated with special thoroughness.

dismissed as a triviality. In the more recent treatment system formulations for early syphilis, emphasis is laid on the serologic positivity of the blood

persisting beyond the twenty fourth week *as strong evidence of the existence* of neurosyphilis and the need for a spinal fluid examination On the other hand, a *negative* blood and spinal fluid may early in the disease accompany grave neurosyphilitic accidents, especially neuroretinitis (see Fig 405) and vascular lesions of the brain. The Cooperative Group found that there is a definite relationship between spinal fluid abnormality in early syphilis and the blood serologic reaction. The more marked the fluid abnormalities, the more likely is the SWR to be positive. Blood serologic fastness occurs in only 16 per cent of patients with negative spinal fluids. More than 40 per cent of those patients whose fluids showed a positive Wassermann reaction are Wassermann-fast in the blood.

When Shall the Spinal Fluid Examination in Early Syphilis Be Made?— The spinal fluid examination of the patient with early syphilis should not be performed until at least one and preferably two doses of arsphenamine or its equivalent have been administered, to prevent *transfer of infection from the blood stream.*

A spinal fluid examination on every patient with early secondary syphilis during the first two weeks of the first course preferably coincident with the third injection of an arsenical establishes a base-line for subsequent tests, and for the detection of those precocious severe involvements which will demand unusually vigorous treatment. Under the conditions of out-patients city clinic work a compromise with ideal conditions must be made, the fluid being examined toward the end of the first year of *continuous* treatment or before a rest interval is granted. The later the case when first seen, the more important the early examination of the fluid for the type of treatment may depend on it. If the patient with secondaries cannot be induced to accept an early spinal test, the next most essential time for the performance of puncture is the twenty-fourth week in alternating systems before the patient is placed on *subintensive treatment such as bismuth alone. It is during this interval* that any damage to his resistance will make itself felt if the infection has not been completely suppressed. The key to an impending neurorecurrence from a seemingly clear sky can often though not always be found at this time even though there are no clinical symptoms whatever Especial emphasis is to be laid on the slight rises in cell count. The end of the first or second course is the time commended by Moore and Keidel for examination of the spinal fluid because experience shows pretty definitely that the patient who has a positive fluid at this time will require more than ordinary treatment measures to reduce *him to normal. In the foreshortened intensive treatment systems* (five days to twelve weeks) spinal fluid examination between the sixth and twelfth month after treatment begins is advised.

THE CLINICAL PICTURE OF EARLY NEUROSYPHILIS

In Fig. 404 an attempt is made to parallel the pathologic process in the nervous system with the patient's symptoms in each of the recognized forms of early neurosyphilis. The parallelism of this series of clinical lesions with the list of recognized neurorecurrences simply expresses the essential identity of the two processes, as will be explained.

The various lesions tabulated are not at all mutually exclusive, and a diffuse meningeal or encephalitic process may be varied by additional signs of focal involvement, especially of the cranial nerves.

Headache is an important symptom of meningeal irritation in early syphilis, and, *if persistent, calls for a spinal fluid examination on suspicion*. The striking findings which may develop on what seem to be very trifling clues are well illustrated in Fig 541 The group of papules on the palm (lues cornée) was the clue to a meningeal involvement whose expression in headache had sent the patient originally to the gynecologist. The identification of her *ailment brought her husband Fig 414 under observation with his fourth* cutaneous relapse and a resistant neurosyphilis. The moderate grades of meningismus may be mistaken for rheumatic torticollis on account of the stiffness of the neck. Cases with projectile vomiting from intracranial pressure may pass for brain tumor before the blood and spinal fluid are examined.

That there is no necessary correlation between the severity of meningeal symptoms and the cell count in the spinal fluid has been evident in our experience Cell counts as high as 300 to 400 per cubic millimeter have occurred

Fig. 404.

PATHOLOGY AND CLINICAL SYMPTOMATOLOGY OF EARLY NEUROSYPHILIS

Pathologic process.	Clinical symptoms.	Clinical signs.
Basilar meningitis (diffuse)	Headache and head pain, stiff neck, nausea, vomiting.	Fundus examination may show optic neuritis, or choked disk from chiasm involvement or increased intracranial pressure
Basilar meningitis, localized.	Focal symptoms depending on location of lesion (see below)	Focal signs from involved cranial nerves.
Diffuse meningo-encephalitis.	Acut neurasthenia nd anxiety states. Em ti nal d hysterical states. Mental confusion, delirium, maniacal states. Coma, often of sudden onset. Incontinence	Irritative signs, increased reflexes, Babinski sign Paralyses. Loss of sphincter control. Pupillary changes, sluggishness, fixation, inequality Coma. Localizing or focal symptoms from involved cranial nerves.
Acut early syphilitic myelitis.	First symptom usually urinary retention requiring catheter Anesthesia Total paralysis usually of lower extremities with later extension	Wide-spread irritative signs (increased reflexes) followed by sensory *disturbances and* flaccid paralysis.
Syphilitic epilepsy	Epileptiform convulsions	May present Jacksonian or other localizing signs of area involved No residual paralysis.
Early syphilitic apoplexy	Weakness, numbness, or paralysis, arm, leg, opposite side of face	Hemiplegia, usuall partial recovery
Cranial nerve lesions. N VIII (auditory) (cochlear nerve)	Tinnitus, *unilateral or bilat*eral, impairment of hearing, especially for high tones. Ma bear conversation at first.	Lowered *high forks* decreased bone conduction; tone islands. Deafness, partial or complete, slow or sudden, permanent or temporary

Fig. 404 (Continued)

Pathologic process.	Clinical symptoms	Clinical signs.
N VIII (vestibular) Cochlear and vestibular lesions may occur together	Vertigo, nausea, vomiting	Nystagmus, falling t one side, past-pointing. Bárány findings.
N. VII.	None inability to whistle or to close one eye.	Lagophthalmos corner of mouth droops on affected side. Mouth pulls toward unaffected side.
N II.	May be no complaint from slight lesions. Falling vision, scotomata if marked. Symptoms of intracranial pressure in some cases.	Papillitis, exudate; vitreous opacities, central scotoma. Choked disk.
N III.	Diplopia.	If partial, may be only weakness of internal rectus. Nuclear paralyses may affect only extra-ocular muscles. Total paralysis produces ptosis, outward deviation of eyeball, face upward and toward one side, head inclined to shoulder of paralyzed side. Slight exophthalmos, pupil dilated and fixed. Accommodation paralyzed.
N IV	Diplopia.	Eye deviates upward and slightly inward. Face directed downward and toward sound side. Limitation of movement downward and toward paralyzed side.
N VI	Diplopia.	Convergent squint, face turned toward paralyzed side. (External rectus paralysis.)
N V	Anesthesia, sometimes with some preceding neuralgia, over areas innervated by this nerve. Corneal disturbances. Cheek biting.	Anesthesia over areas supplied, including conjunctiva and palate Paralysis of muscles of mastication. Neuroparalytic keratitis.

in patients with no symptoms. Zimmermann calls attention to the fact that a high cell count may be produced by a focal lesion without general involvement of the meninges. The symptomatology of the meningo-encephalitic and vascular lesions is described in Chapter XX.
